The Mack Printing Co., Easton, Pa.

# Foreword

IN INTRODUCING to researchers in engineering the present volume of the TRANSACTIONS of The American Society of Mechanical Engineers, an explanation of the changes which have taken place in its physical appearance and its contents is due.

## CHANGE IN PUBLICATION POLICY

A revision of the publication policy of the A.S.M.E. consummated in 1928 resulted in important changes in the TRANSACTIONS. Physically, the page size was increased to conform to that of the Society's journal *Mechanical Engineering*. In order to bring the published papers of the Society more quickly to its members, and to bring to each member only the papers in which he had an interest, the old plan of publishing once a year a single volume, expensively bound and sent without charge to every member of the Society, was abandoned in favor of a radically different scheme.

The new plan provides for the issuing in pamphlet form of groups of selected papers presented at meetings and other miscellaneous contributions. These pamphlets, forming sections of the TRANSACTIONS, are issued periodically at the rate of about three a month, and each section is sponsored by one of the Society's professional divisions.

The new plan has made possible a change in the principles underlying the selection of papers for inclusion in the TRANSACTIONS. Under the old plan, publication was delayed by the custom of printing but once a year, and this delay, combined with the expense, limited the choice of papers to a relatively few which were considered to be of permanent reference value. Much valuable material which could not be presented in the Society's journal, *Mechanical Engineering*, was therefore excluded from publication.

Under the new plan a member of the Society may register in any three professional divisions and may receive, without cost, the sections of the TRANSACTIONS which are sponsored by these divisions. The periodical publication of these sections in magazine form has a feature of timeliness which justifies the inclusion of papers of possible temporary interest. It also offers a medium for the printing of papers of specific interest to a single group of members without the cost of distribution to all.

The new policy, combined with increased activity on the part of the professional divisions, has made available a much greater number of engineering papers, as may be judged by comparing volume 48 (1926) with its 38 papers and the present volume with its 257 papers.

## COMPLETE TRANSACTIONS FOR DEPOSITORIES AND LIBRARIES

For permanent record and for reference use in libraries, and in the Society's depositories all over the world, a number of sets comprising all of the sections of TRANSACTIONS have been provided. When each section of the TRANSACTIONS was printed, extra impressions were laid aside, and these have been bound in the two books which form parts I and II of volume 49–50.

## Volumes 49 and 50 Published Together as Volume 49-50

The valuable feature of a shorter time interval between the presentation of a paper and its publication under the new plan made it possible to publish the papers which would have comprised volumes 49 (1927) and 50 (1928) under the old plan simultaneously during 1928 without delaying the appearance of the 1927 papers. (Under the old plan volume 49 would have appeared in book form in the summer of 1928.)

The division of the complete Transactions into two books known as parts I and II is for convenience in binding and does not differentiate volumes 49 and 50. No differentiation exists. The combined volume is known as volume 49-50 (1927-1928). In numbering the papers in accordance with the scheme outlined below, all papers are referred to as of volume 50.

## Numbering of Papers and Arrangement in Complete Transactions

The definite sponsorship of every paper by one of the professional divisions has led to the abandonment of the former system of numbering papers serially. The new system designates each paper by a symbol composed of key letters and significant numbers. The letters refer to the section of Transactions to which the paper is assigned. Thus AER refers to the Aeronautic section, IS to the Iron and Steel section, etc. The first number which follows the letters is the volume number, as volume 50, and the second is the serial number within the section of the paper in question. Thus FSP-50-3 indicates that the paper so numbered is a part of the Fuels and Steam Power section of volume 50 of Transactions, and is the third paper of that series. The arrangement of papers in the bound Transactions is alphabetical by sections, and numerical within the section. All papers of the Management section, for instance, will be found together in numerical order under the symbol MAN.

## How to Use the Index

In each of the two books forming parts I and II of volume 49-50 will be found a complete index to both parts of the volume so that either may be consulted. Reference to the individual items comprising the index is by paper number, explained above, the page number being included in parentheses. Thus MH-50-8 (15) means that the reference is to be found in the Materials-Handling section, vol. 50, paper no. 8, page 15. In part I of the bound volume are all papers belonging to sections whose key letters are between AER and FSP, and in part II all those whose key letters are between HYD and WDI.

## Concerning Blank Pages

In order to make the papers comprising the Transactions available as reprints, it is necessary to print them so that the number of pages they contain is a multiple of four. This accounts for the blank pages which will be found scattered throughout the volume.

The Publications Committee.

# Progress in Hydraulics

## Contributed by the Hydraulic Division

Executive Committee: Ely C. Hutchinson, *Chairman*, H. L. Doolittle, *Secretary*, H. Birchard Taylor, R. L. Thomas, and W. M. White

THE YEAR 1927 has seen marked progress in practically all branches of industry related and of interest to the Hydraulic Division. The country as a whole has enjoyed an increased growth somewhat better than normal. While there has been no one thing outstanding, a review of what has happened during the year indicates a distinct trend.

The light and power industry in which the membership of the Hydraulic Division centers the greater part of its activity, is serving close to a million and a half new customers since the date of our last progress report. The greatest increase has been in the number of domestic-lighting customers. The increase in the use of industrial power and commercial-lighting power has nevertheless been well maintained and shows a healthy increase. In particular, the growth in the use of electricity in the rural districts is worthy of special mention.

### Economic and Political Aspects

The economics of electric-utility operation is receiving increased attention, and one of the results of this is an increase in the interconnection of electric systems. There are now in fact eighteen electric systems in the United States each having an annual output of one billion kilowatt-hours or more.

Increased efficiency in the operation of steam plants in combination with moderate- or low-priced fuels, has brought steam-power-plant operation to the point where in some cases it is economically the equal of, or superior to, hydro-generated power. While this condition has resulted largely from the fact that cheap water powers are becoming increasingly more difficult to find, it has also had the effect of introducing intensive economic studies as to the relationship and relative value of steam- and water-generated power.

A number of studies by outstanding engineers have been published upon this subject during the past year under the auspices of The American Society of Mechanical Engineers; The Franklin Institute, Philadelphia; and The National Electric Light Association and its Pacific Coast affiliate, The Pacific Coast Electrical Association. A. H. Markwart, vice-president in charge of engineering of the Pacific Gas & Electric Co. of San Francisco, is the originator of an outstanding method for studying and properly evaluating the relative uses of steam and hydro power. It is the opinion of all students of the subject that the position of hydro power is economically difficult. Under the analytical method of Mr. Markwart, however, it becomes immediately clear that with certain relations between the capital cost of water power and fuel prices, although the cost of an all-hydro supply may be less than the cost of an all-steam supply, the cost of a combined hydro and steam supply is even less than the cost of an all-hydro supply; and conversely, with certain other relations, although the cost of an all-steam supply may be less than the cost of an all-hydro supply, the cost of a combined steam and hydro supply will be less than the cost of an all-steam supply. The practical application of these facts is apparent both East and West, and water-power developments are being examined from an enlightened economic viewpoint. A marked example of this is present in the U.G.I. installation at Rocky River, Connecticut. Eight thousand-horsepower vertical pumps have been installed for the utilization of off-peak power to elevate water to a storage reservoir for use in peak-load service. By this means a better balance of output is secured and a greater operating economy results. Although this plan of operation was used on a small scale very nearly twenty years ago in California and is quite generally used abroad, the U.G.I. installation is notable as being the first of such magnitude in this country.

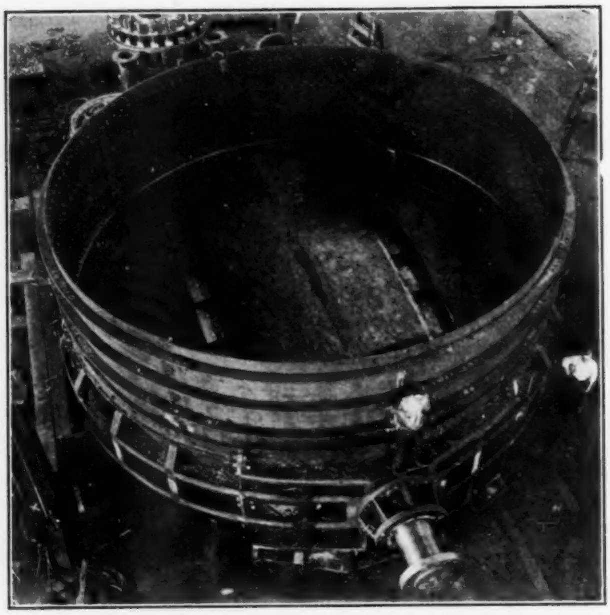
It is very evident also that the economic position of hydro power is well understood and appreciated by the manufacturers of hydraulic-power machinery. Numerous studies in the engineering departments, laboratories, and in the field are being made by the leading manufacturers for the purpose of securing increased economy in hydro-power machinery. Results of this work will continue to be of untold benefit to industry and to the country as a whole. Work of this sort is, however, deplorably handicapped by failure on the part of a large number of central-power or public-utility companies to appreciate that the funds for carrying on such work must come from and be included in the sale of the machinery they purchase. Despite the fact that the prices obtainable by manufacturers for hydraulic-power machinery have been extremely poor, an effort has nevertheless been made to carry on their research and economic studies. Much greater advance would undoubtedly be made, however, and greater benefit will inevitably result, if some plan may be worked out between the purchasers and the manufacturers under which the manufacturers may be placed in funds as a result of their industry, with which to carry on their efforts upon a major scale. An exceptional few of the utility companies have practiced this policy, and no doubt know that the results secured have been ample recompense.

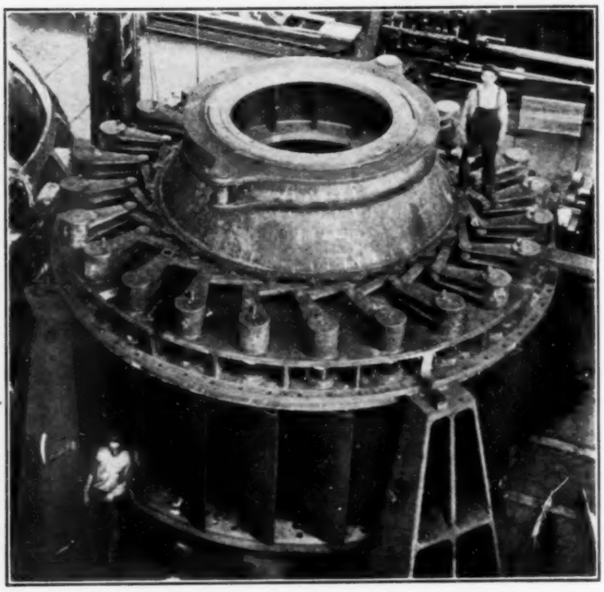
The administration and regulation of our water-power resources by the Federal Power Commission have been generally acceptable to the people and accepted by the public utilities. The introduction of discussion and agitation in some directions toward interstate regulation of large projects such as the St. Lawrence, Tennessee, and Colorado Rivers is apparent.

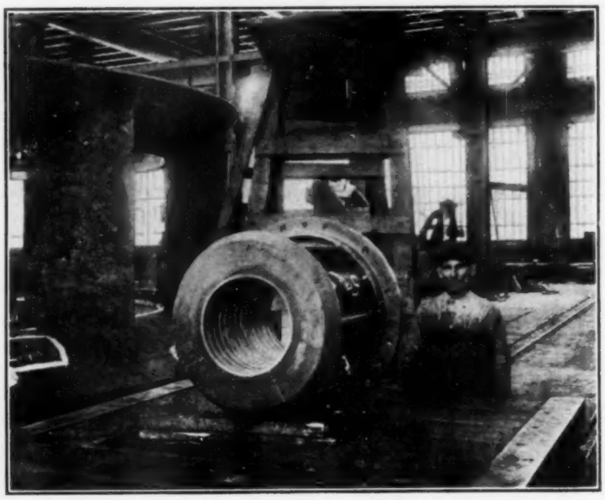
The discontinuance of some municipalities in the hydro-electric-power field is noted, and their activities continue in some other parts of the country, notably in Los Angeles and San Francisco.

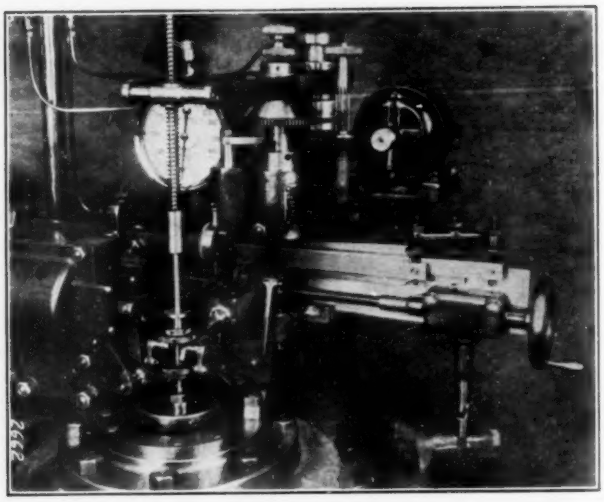
The findings in the so-called "Indianapolis Water Rate Case" are worthy of special mention. The Indianapolis Water Company, which is understood to be the third largest individual water company in the United States, brought suit to enjoin the Public Service Commission of Indiana, its members, and the City of Indianapolis from putting into force certain water rates on the ground that the fixed rates were confiscatory. The adjudication which followed and final decision which was rendered by the United States Supreme Court, November 22, 1926, is of special interest to the membership of the Hydraulic Division as it has set forth for the first time in the history of the United States Supreme Court definite principles having to do with the method of evaluating properties. The text of the entire decision is recommended to those who are further interested. The outstanding points, however, are contained in the following quotations from the majority opinion.

1 In determining present value, consideration must be given to prices and wages prevailing at the time of the investigation, and in









Above: Shop Assembly of 27-Ft. Pivot Valve, Conowingo Development

Below: Rubber-Lined Guide Bearing for 5000-Hp. Turbine

Above: Shop Assembly of 54,000-Hp. Turbine for Conowingo Development

Below: Automatic Control Features Provided for 17,000-Hp. Pelton Wheel

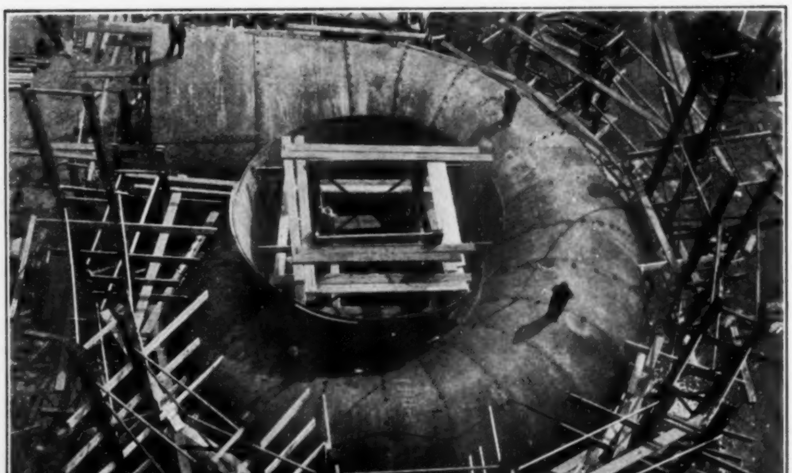


Plate-Steel Volute Casing for 54,000-Hp. Turbine, Conowingo Development

the light of all the circumstances there must be an honest and intelligent forecast as to the probable price and wage levels during a reasonable period in the immediate future.

2 Re depreciation: The testimony of competent valuation engineers who have examined the property and made estimates in respect of its condition is to be preferred to mere calculations based on averages and assumed probabilities.

3 A reasonable rate of return is not less than seven per cent.

The opinion emphasizes also the necessity of including value of water rights, going-concern value, and working capital in a proper evaluation. Although it has been customary for some years for experts to give testimony of their own conclusions as to the proper rate or percentage of depreciation to be deducted in evaluation cases, such conclusions being based upon actual inspection by the experts themselves, it is believed that no former opinion has so emphasized the justice of this method. Because of the clarification of the entire matter of evaluations as a result of the opinion, it has been deemed advisable to make special mention of the case so that those further interested may secure the entire text for further study.

Substantially cognate questions are involved in the recent decisions in the Kansas City Gas Co. case and the still more interesting case of the St. Louis & O'Fallon Railroad Co. The entire matter is so important that there is no doubt that it will come, and probably within not too long a time, before the U. S. Supreme Court.

### Improvements in Hydro-Power Machinery

A review of the year's progress does not bring special emphasis upon any outstanding mechanical improvement in hydro machinery. Intensive study has, however, been given to the improvement of existing designs in which advantage has been taken of operating experience. Knowledge of the comparative remoteness of remaining undeveloped hydro-power sites and their consequent high cost of development has given direction of thought among leaders of the industry to the necessity for simplification and economy of operation in hydroelectric installations. It is recognized that economy of plant operation is best secured with equipment which will operate most continuously and with the least expenditure for maintenance and renewals. To increase the existing knowledge, intensive studies are being made of the operation of power plants both steam and hydroelectric.

The outages of plants (or units), their causes, maintenance, and operating costs are being scrutinized and their relation to first cost of apparatus determined. In hydroelectric plants the economy of water consumption is receiving first attention. Air is being introduced into turbines automatically and otherwise, with the result that their no-load efficiency has been increased to a great extent when generators are floated on the line for the improvement of power factor. This method of operation has received much attention and its development has resulted in the elimination of a large percentage of stand-by leakage through turbines. It has become almost universal practice to make accurate tests of water wheels and turbines after installation to determine their operating characteristics. Information secured as a result of these tests is used to great advantage in developing the most economical method of plant operation in connected systems, the hydraulic conditions also being considered.

Voltages and frequencies are undergoing gradual standardization. This work must lead that of further and future interconnections.

The flow of streams that are subject to wide seasonal variations is being utilized to increased advantage by adding induced capacity to hydraulic turbines by means of backwater suppressors and ejector turbines. A great deal of attention is being paid to the improvement of turbine operation under variable heads. This problem has been more actively met in the European plants than in the United States, and instances of notable results secured have been published in the technical press. The most promising results have been secured in obtaining high efficiencies over widely varying heads by means of turbines having adjustable-bladed runners operated independently and in some cases automatically.

Propeller-type turbines are being successfully operated with stability and good regulation under increasingly higher heads, and efficiencies are ranging upward to ninety-two and ninety-three per cent.

Development of the use of rubber in various places is continued. Experience is increasing in the use of rubber seal rings for turbine runners. Rubber seals have been introduced as a means for decreasing the leakage around guide vanes when in closed position for the purpose of decreasing shutdown losses. Rubber is being applied to the periphery of large butterfly valves, and marked success is being secured in decreasing of water leakage by this method. Several cases are on record in which water-lubricated rubber bearings have been used with great success in turbines. Bearings of this type have replaced lignum vitae, with much better wearing results.

Much is being done to eliminate outage of hydroelectric plants from failure of the governor driving belt. Development in this direction is being manifest in the operation of the centrifugal elements of the governors by means of direct gear connection and electric motor. Other designs provide for mounting the centrifugal element directly upon the shaft of the prime mover.

Spiral casings for turbines which operate under moderate heads are being made of plate steel, with the joints in some cases being electric-welded in place at point of installation as means of securing more permanent water-tightness than by calking.

As a means of maintaining the turbine runner in its exactly central position, a hemispherical combined thrust and turbine guide bearing to the design of Albert Kingsbury may shortly be tried.

A measure of economy and increased reliability is being manifested in the electric welding of plate steel and rolled structural-steel forms into the frames or stators of large generators for which castings of iron or steel have been hitherto used almost exclusively.

Means for maintaining a perpetual check upon hydroelectric-power-plant operation, both electrically and hydraulically, are being permanently installed in the power plants and are rapidly proving their value as an aid to the maintenance of the best operating efficiencies at all times.

The value of full automatic and semi-automatic operation of water-power plants is assured, and a great economy has been effected by their use. As a result, smaller water-power sources hitherto undeveloped or found to be very expensive to operate are being brought into service upon an economical basis.

### Other Improvements in Hydroelectric-Plant Construction

Of the improvements in hydroelectric-plant construction other than those which have taken place within the power house itself, several developments are worthy of special mention. The so-called "Johnson-Wahlmann intake" for admitting water into conduits is being installed. Its use is of special advantage in the avoidance of ice troubles at the intake and diversion works.

For high-head developments where the purpose of finding a suitable and safe penstock construction at reasonable cost has been a particularly vexing one, a solution has apparently been found in the development of centrifugally cast and cross-roll-forged seamless steel piping. The installation of expensive plant machinery for the manufacture of this pipe of high-grade steel in sizes from thirty-two inches up to any diameter which may be

shipped, and in thicknesses varying from one-half inch up to five or even six inches, is assured and will undoubtedly mean much to the economic possibility of installing high-capacity, high-head, hydroelectric power plants.

In the case of tunnels lined with concrete a most important development has been that of the Hackley pneumatic apparatus for forcing concrete behind the forms of tunnels. This apparatus deposits the concrete without segregation and in horizontal layers in a very effective manner, up to and including even the crowns of the arches.

The fact that 220,000-volt transmission is now a demonstrated success as to reliability and economy, will undoubtedly mean much in the development of water-power projects which have hitherto been considered not economically accessible. Crest gates are being increasingly used as a means of maintaining the most economical hydraulic conditions for plant operation.

There has been wide development in the use of Johnson needle valves as an economical means for stream and storage-reservoir regulation. Valves of this type are becoming the accepted standard in this service.

### The Broader Possibilities of Economic Hydroelectric-Plant Construction

In the light of the present advanced state of the art there is no doubt that there are numerous old plants operating in systems and under comparatively ancient water-power concessions that can well afford to be rebuilt or modernized. A study of such possibilities will in numerous cases prove to offer a handsome return upon the capital investment required. Another, and probably the source of the greatest opportunity for economic hydraulic power, lies in the complete and balanced development of entire streams and watersheds into a single project. There are probably numerous cases where the existence of isolated power developments has served to distract attention from the possibilities of a river or watershed which would be readily apparent if existing developments were removed from the picture. An effort should be made to uncover these and analyze their possibilities in the light of present-day knowledge.

### Research

Research in the field of hydraulics is continuing in many directions. One of the outstanding projects in this respect is the Stevenson arch-dam investigation. This consists of an elaborate test upon a full-sized model arch dam made of concrete and having a height of approximately sixty feet, a thickness near the crest of about two feet, and a length at the crest of one hundred and sixty-five feet. This dam has been installed on Stevenson Creek, California, on the system of the Southern California Edison Co., under conditions comparable to those met in actual installations, and has been provided with means for scientific observations. The knowledge gained is already proving of great benefit. The work is being done under the auspices of the Engineering Foundation and is assisted by a notable group of contributors and cooperators, including the United States Bureau of Standards.

Research with the aid of small-scale models is increasing, and there are many notable examples of this, such as the Niagara Falls Power Co. model for the investigation of the proposed remedial works for the preservation and improvement of the scenic grandeur of Niagara Falls with the possibility of diverting more water for power purposes; the Chelan dam development of the Washington Water Power Co.; and the observation of surge-chamber phenomena at the Pit No. 3 development of the Pacific Gas & Electric Co. The Niagara Falls Company has undertaken extensive research in connection with its operations for the purpose of determining the friction losses in large concrete-lined tunnels.

Research is also being carried on for the enlargement of knowledge for the purpose of intake design; draft-tube construction; the determination of spiral or scroll-case forms for turbines; enlargement of the knowledge of causes of turbine-runner pitting, and many other live subjects.

A very constructive work has been done by Ray S. Quick in his analysis entitled "Comparison and Limitations of Various Water-Hammer Theories." The complete text of Mr. Quick's paper was read at the Spring Meeting of The American Society of Mechanical Engineers at White Sulphur Springs, West Virginia, in May, 1927.

A matter in which there is still much to be done is the investigation of the causes of corrosion in penstocks. It is hoped that this will receive greater attention than it has in the past.

### Conclusion

The field of hydroelectric power is one of great promise and intense interest. The development of the market for electricity exhibits a healthy and encouraging increase. Activity in the works of irrigation and reclamation not only provides a market for electricity, but offers an inviting field to the builders of water-regulating and pumping equipments. There is vast opportunity for the users of hydraulic machinery of all kinds to co-operate with its builders and for the development of a purchasing policy which will give full recognition to the fact that the interests, aims, and desires of all are closely related. More complete realization of these mutual interests will inevitably lead to the greater progress for which we are all striving.

Ely C. Hutchinson, *Chairman.*

# A New Method of Separating the Hydraulic Losses in a Centrifugal Pump

## Particulars of a Method by Means of Which the Friction and Shock Losses of a Given Pump May Be Determined Separately from Its Head-Capacity Curve, Together with Illustrative Example

By MICHAEL D. AISENSTEIN,[1] BERKELEY, CALIF.

The so-called hydraulic losses in a centrifugal pump are composed of friction losses and shock loss. The friction losses are those which are due to resistance offered to the water by the walls of the runner and case. The shock loss may be considered as due to the sudden enlargement of passages.

It is important for the designer to know how the losses are distributed and to have a method of separating them, so that by studying the variation of these losses he may decide in which direction improvement should progress.

The purpose of this paper is to present a method by means of which these losses may be determined separately from the head-capacity curve of a given centrifugal pump.

The following symbols and nomenclature are used:

$d_1$ = diameter at inlet of impeller in feet
$d_2$ = diameter at outlet of impeller in feet
$k$ = coefficient of head loss
$c_1$ = absolute velocity of water at entrance of impeller, feet per second
$c_2$ = absolute velocity of water at exit of impeller, feet per second
$w_1$ = relative velocity of water at inlet of impeller, feet per second
$w_2$ = relative velocity of water at outlet of impeller, feet per second
$v_d$ = velocity in volute case referred to $d_2$, feet per second
$\omega$ = angular velocity in radians
$T$ = torque in foot-pounds
$L$ = power in foot-pounds per second
$M$ = moment of momentum
$u_1$ = peripheral velocity of impeller at inlet, feet per second
$u_2$ = peripheral velocity of impeller at exit, feet per second
$a$ = area in square feet
$t$ = vane thickness at periphery in feet
$z$ = number of vanes
$\delta$ = vane angle (fixed)
$\theta$ = water angle
$b_1$ = breadth between the impeller disks or shrouds at the diameter $d_1$ in feet
$b_2$ = breadth between the impeller disks or shrouds at the diameter $d_2$ in feet
$\gamma$ = weight of 1 cubic foot of water
$Q$ = capacity in cubic feet per second
$h$ = head in feet
$H$ = theoretical head in feet for an impeller with a finite number of vanes
$H_{\text{inf.}}$ = theoretical head in feet for an impeller with an infinite number of vanes.

Let $T$ = torque exerted on the impeller. Then, neglecting the losses,

Torque = change in the moment of momentum

$$T = \Delta M$$

or

$$T = \frac{Q\gamma}{g}(r_2c_2\cos\theta_2 - r_1c_1\cos\theta_1) \qquad [1]$$

Calling

$$c_2\cos\theta_2 = c_{u2}$$

and

$$c_1\cos\theta_1 = c_{u1}$$

Equation [1] can be rewritten as

$$T = \frac{Q\gamma}{g}(r_2c_{u2} - r_1c_{u1}) \qquad [2]$$

This is the torque given to the water by the shaft. Multiplying both sides of Equation [2] by the angular velocity $\omega$,

$$T\omega = \frac{Q\gamma}{g}(r_2\omega c_{u2} - r_1\omega c_{u1})$$

or since

$$T\omega = L = \text{power}, \quad r_2\omega = u_2, \quad \text{and } r_1\omega = u_1,$$

$$L = \frac{Q\gamma}{g}(u_2c_{u2} - u_1c_{u1}) \qquad [3]$$

The power is also equal to the weight of the fluid raised per second against the head $H$, so that

$$L = Q\gamma H \qquad [4]$$

Equating Equations [3] and [4],

$$Q\gamma H = \frac{Q\gamma}{g}(u_2c_{u2} - u_1c_{u1})$$

or

$$H = \frac{u_2c_{u2} - u_1c_{u1}}{g} \qquad [5]$$

which is the fundamental equation of a centrifugal pump.

The losses in a centrifugal pump may be classified as

*a* Friction losses and
*b* Shock loss.

The friction losses are approximately proportional to the square of the capacity and may be expressed as

$$h_f = CQ^2 \qquad [6]$$

The shock loss, which is due to the sudden enlargement of passages, may be represented by

$$h_s = \frac{k_s(c_{u2} - v_d)^2}{2g} \qquad [7]$$

---

[1] Hydraulic Engineer, Byron Jackson Pump Mfg. Co. Jun. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of The American Society of Mechanical Engineers. All papers are subject to revision.

and the actual head produced by the pump will be

$$h = H - h_f - h_s$$

$$= \frac{u_2 c_{u2} - u_1 c_{u1}}{g} - CQ^2 - \frac{k_s(c_{u2} - v_d)^2}{2g} \quad \ldots\ldots [8]$$

But

$$c_{u2} = u_2 - \frac{c_{r2}}{\tan \delta_2} \quad \ldots\ldots [9]$$

and

$$c_{u1} = u_1 - \frac{c_{r1}}{\tan \delta_1} \quad \ldots\ldots [10]$$

also

$$c_{r2} = \frac{Q}{(\pi d_2 - z t_2)\, b_2} \quad \ldots\ldots [11]$$

and

$$c_{r1} = \frac{Q}{(\pi d_1 - z t_1)\, b_1} \quad \ldots\ldots [12]$$

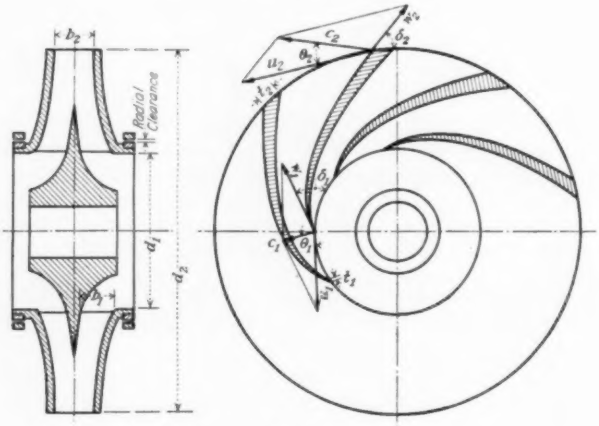

Fig. 1

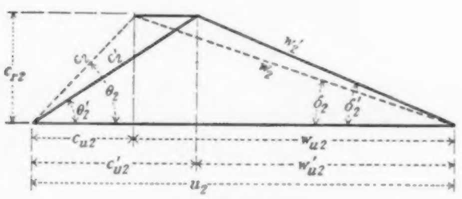

Fig. 2

Substituting Equations [9] to [12] in Equation [8] and remembering that $v_d = Q/a_3$, where $a_3 = a_3' \, d_2/d_3'$,

$$h = \frac{u_2^2 - \dfrac{u_2}{(\pi d_2 - z t_2) b_2 \tan \delta_2} Q - u_1^2 + \dfrac{u_1}{(\pi d_1 - z t_1) b_1 \tan \delta_1} Q}{g}$$

$$- CQ^2 - \frac{k_s \left[ u_2 - \dfrac{Q}{(\pi d_2 - z t_2)\, b_2 \tan \delta_2} - \dfrac{Q}{a_3} \right]^2}{2g} \quad \ldots\ldots [13]$$

or

$$h = \left[ \frac{u_2^2 - u_1^2}{g} \right] + \left[ \frac{\dfrac{u_1}{(\pi d_1 - z t_1) b_1 \tan \delta_1} - \dfrac{u_2}{(\pi d_2 - z t_2) b_2 \tan \delta_2}}{g} \right] Q$$

$$- CQ^2 - \left[ \frac{\sqrt{k_s}}{\sqrt{2g}} u_2 - \frac{\sqrt{k_s}}{\sqrt{2g}} \left\{ \frac{1}{(\pi d_2 - z t_2) b_2 \tan \delta_2} + \frac{1}{a_3} \right\} Q \right]^2 \quad \ldots\ldots [14]$$

For a given pump running at a constant speed, all the bracketed quantities in Equation [14] are constant as they depend on the physical dimensions of pump; therefore we may write

$$h = A + BQ - CQ^2 - (D - EQ)^2 \quad \ldots\ldots [15]$$

where $CQ^2$ is the friction loss and $(D - EQ)^2$ is the shock loss, and

$$A = \frac{u_2^2 - u_1^2}{g} \quad \ldots\ldots [16]$$

$$B = \frac{\dfrac{u_1}{(\pi d_1 - z t_1) b_1 \tan \delta_1} - \dfrac{u_2}{(\pi d_2 - z t_2) b_2 \tan \delta_2}}{g} \quad \ldots\ldots [17]$$

$$D = \sqrt{\frac{k_s}{2g}} \times u_2 \quad \ldots\ldots [18]$$

$$E = \frac{k_s}{2g} \left\{ \frac{1}{(\pi d_2 - z t_2) b_2 \tan \delta_2} - \frac{1}{a_3} \right\} \quad \ldots\ldots [19]$$

Expanding Equation [15],

$$h = A + BQ - CQ^2 - D^2 + 2DEQ - E^2Q^2$$

or

$$h = (A - D^2) + (B + 2DE)Q - (C + E^2)Q^2 \quad \ldots\ldots [20]$$

and calling $A - D^2 = A'$, $B + 2DE = B'$, and $C + E^2 = C'$,

$$h = A' + B'Q - C'Q^2 \quad \ldots\ldots [21]$$

The constants $A'$, $B'$, and $C'$ can be determined from an actual head-capacity curve, as will be shown later in an example, and as above stated,

$$A' = A - D^2 \quad \ldots\ldots [22]$$

$$B' = B + 2DE \quad \ldots\ldots [23]$$

$$C' = C + E^2 \quad \ldots\ldots [24]$$

The theoretical head when computed by means of Equation [5] is always higher than the actual theoretical head:

$$H = h + \text{losses} \quad \ldots\ldots [25]$$

Referring to Fig. 2, because the number of vanes is finite the particles of water do not follow the vane angle $\delta_2'$ but follow a certain average angle $\delta_2$ which is smaller than $\delta_2'$. Consequently $c_{u2}$ is less than $c'_{u2}$, and if the theoretical head with an infinite number of vanes is

$$H_{\text{inf.}} = \frac{u_2 c'_{u2} - u_1 c_{u1}}{g} \quad \ldots\ldots [26]$$

the theoretical head with finite number of vanes is

$$H = \frac{u_2 c_{u2} - u_1 c_{u1}}{g}$$

Hence Equation [17] cannot be used in this form unless the angle $\delta_2$ is corrected.

Since the maximum efficiency occurs practically at a point where the hydraulic losses are minimum, that is, where the sum of the friction losses and shock loss is a minimum,

$$Y = CQ^2 + (D - EQ)^2 = \text{minimum} \quad \ldots\ldots [27]$$

The value of $Q$ which makes $Y$ a minimum must satisfy the condition $dY/dQ = 0$; hence, differentiating Equation [27] with respect to $Q$ and equating it to zero,

$$2CQ + 2(D - EQ)(-E) = 0$$

or

$$CQ - DE + E^2Q = 0 \quad \ldots\ldots [28]$$

From Equation [24]

$$C = C' - E^2$$

Substituting this value of $C$ in [28]

$$C'Q - E^2Q - DE + E^2Q = 0$$

or

$$C'Q = DE \ldots\ldots\ldots\ldots\ldots\ldots\ldots [29]$$

where $Q$ is the rate of discharge at the point of maximum efficiency.

We now have five equations, [16], [22], [23], [24], and [29] and five unknowns $A$, $B$, $C$, $D$, and $E$. Hence from given characteristics obtained from an actual test it is possible by simple substitution of different values of $Q$ to determine the friction losses $CQ^2$ and the shock loss $(D - EQ)^2$. An example illustrative of the use of these equations follows.

### Illustrative Example

Let Fig. 3 represent an actual test of a 5-in. double-suction single-stage centrifugal pump running at 1750 r.p.m. The inlet

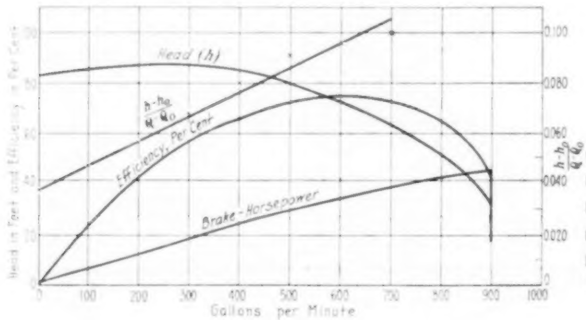

Fig. 3

diameter of the impeller $d_1 = 4^3/_8$ in., and the outlet diameter $d_2 = 9$ in.

Let us tabulate the values of $Q$ and corresponding values of $h$ from Fig. 3 as in Table 1.

TABLE 1

| No. | $Q$, g.p.m. | $h$, ft. | $Q - Q_0$ | $h - h_0$ | $\frac{h - h_0}{Q - Q_0}$ | $h'$ | $\Delta h$ |
|---|---|---|---|---|---|---|---|
| 1 | 0 | 83 | −800 | 30 | −0.0375 | 83.2 | −0.2 |
| 2 | 100 | 86 | −700 | 33 | −0.0471 | 86 | 0 |
| 3 | 200 | 87 | −600 | 34 | −0.0566 | 87.3 | −0.3 |
| 4 | 300 | 87 | −500 | 34 | −0.0680 | 86.5 | +0.5 |
| 5 | 400 | 85 | −400 | 32 | −0.0800 | 83.8 | +1.2 |
| 6 | 500 | 80 | −300 | 27 | −0.0900 | 79 | +1.0 |
| 7 | 600 | 72 | −200 | 19 | −0.0950 | 72.2 | −0.2 |
| 8 | 700 | 63 | −100 | 10 | −0.1000 | 63.5 | −0.5 |
| 9 | 800 | 53 | 0 | 0 | ..... | 53.1 | −0.1 |

The points $\left[Q, \frac{h - h_0}{Q - Q_0}\right]$ when plotted lie on a straight line (see Fig. 3), which means that these data fit an equation of the form

$$h = A' + B'Q - C'Q^2$$

Using the method of averages and dividing the data into two groups 1, 2, 3, 4 and 5, 6, 7, 8 and adding the $Q$'s and $\frac{h - h_0}{Q - Q_0}$'s for each group, we get

$$4a + 600b = -0.2092$$

$$4a + 2200b = -0.3650$$

Solving for $a$ and $b$,

$$b = -0.973 \times 10^{-4}$$

$$a = -0.0377$$

Substituting these values in

$$\frac{h - h_0}{Q - Q_0} = a + bQ$$

we obtain

$$\frac{h - 53}{Q - 800} = -0.0377 - 0.973 \times 10^{-4}Q$$

Solving this equation for $h$,

$$h = 83.2 + 0.0401Q - 0.973 \times 10^{-4} Q^2$$

This equation is in the form

$$h = A' + B'Q - C'Q^2$$

Substituting different values of $Q$ in gallons per minute, we obtain $h'$ and $\Delta h$, which are tabulated in Table 1.

Next let us determine the constants in Equation [15], having found above that

$$A' = 83.2,\ B' = 0.0401,\ \text{and}\ C' = 0.973 \times 10^{-4}.$$

From Equation [16]

$$A = \frac{u_2^2 - u_1^2}{g}$$

and since from the data given,

$$u_2 = \frac{1750 \times \pi \times 9^1/_2}{720} = 72.4 \text{ ft. per sec.}$$

$$u_1 = \frac{1750 \times \pi \times 4^3/_8}{720} = 33.3 \text{ ft. per sec.}$$

$$A = \frac{72.4^2 - 33.3^2}{g} = 128$$

Solving Equation [22] for $D$,

$$D = \sqrt{A - A'} = \sqrt{128 - 83.2} = 6.7$$

Solving Equation [29] for $E$,

$$E = \frac{C'Q}{D}$$

At the point of maximum efficiency the pump is delivering 600 gal. per min., therefore

$$E = \frac{0.973 \times 10^{-4} \times 600}{6.7} = 0.00872$$

From Equation [24],

$$C = C' - E^2$$
$$= 0.973 \times 10^{-4} - 0.00872^2 = 0.213 \times 10^{-4}$$

From Equation [23]

$$B = B' - 2DE$$
$$= 0.0401 - 2 \times 6.7 \times 0.00872 = -0.0771$$

Substituting all numerical values of coefficients in Equation [15],

$$h = (128 - 0.0771Q) - \underbrace{0.213 \times 10^{-4}Q^2}_{\text{friction}} - \underbrace{(6.7 - 0.00872Q)^2}_{\text{shock}}$$

After $h_f$ and $h_s$ are determined it is possible to calculate the theoretical $H$ (no-loss head) and the hydraulic efficiency $\eta_h$.

$$H = h + h_f + h_s$$

$$\eta_h = \frac{h}{h + h_f + h_s}$$

These results are tabulated in Table 2 and plotted below in Fig. 4.

TABLE 2

| $Q$, gal. per min. | $h$, ft. | $h_f$, ft. $0.213 \times 10^{-4} Q^2$ | $h_s$, ft. $(6.7 - 0.00872Q)^2$ | $H$, ft. $h_f + h_s + h$ | $\eta_h$ per cent |
|---|---|---|---|---|---|
| 0 | 83 | 0 | 45 | 128 | 64.9 |
| 100 | 86 | 0.2 | 33.6 | 119.8 | 71.7 |
| 200 | 87 | 0.8 | 25 | 112.8 | 77.2 |
| 300 | 87 | 1.9 | 16.8 | 105.7 | 82.3 |

| 500 | 80 | 5.3 | 5.3 | 90.6 | 88.2 |
| 600 | 72 | 7.7 | 2.1 | 82.0 | 88.0 |
| 700 | 63 | 10.4 | 0.4 | 73.8 | 85.2 |
| 800 | 53 | 13.6 | 0.1 | 66.7 | 79.5 |
| 900 | .. | 17.2 | 1.2 | ... | ... |
| 1000 | .. | 21.3 | 4.1 | ... | ... |

Analyzing the $h_f$ and $h_s$ losses in Fig. 4, it is seen that the shock loss reaches its minimum value at about 750 gal. per min. This is an indication that the casing of the pump is a little too large. By reducing the areas of the volute casing the point of zero shock loss could be shifted toward the left and the efficiency could probably be improved if the increase in friction loss due to reduction of the casing areas would not offset the decrease in shock loss.

In conclusion, the author would like to point out that many writers on centrifugal pumps define the hydraulic efficiency of a pump as the ratio

$$n_h = \frac{h}{H_{\text{inf.}}}$$

and that the value of the hydraulic efficiency obtained by means of this formula is often less than the actual pump efficiency,

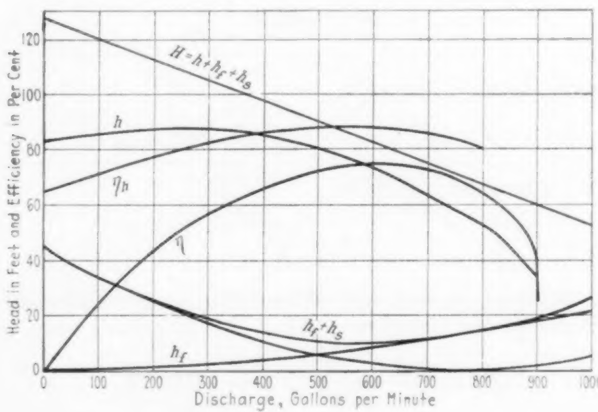

FIG. 4

which includes besides hydraulic losses mechanical losses such as disk friction, friction in stuffing boxes, etc.

The reason for this inconsistency is self-evident when one takes in consideration the fact that $H_{\text{inf.}}$ is never produced by the impeller and is an imaginary quantity because, as was explained, the average actual angle between the relative velocity $w_2$ and peripheral velocity $u_2$ is always less than the casting angle of the vane. Hence the drop from $H_{\text{inf.}}$ to $H$ does not consume any power and is not a loss.

To discuss the factors which influence this "no loss" drop from $H_{\text{inf.}}$ to $H$, the shock and friction losses, is beyond the scope of this paper.

## Discussion

Robert W. Angus.[2] The paper presents an interesting problem on the centrifugal pump, and one to which little attention has recently been paid. Earlier writers on centrifugal pumps went into the distribution of the losses with much care and some interesting discussion of the question will be found in the paper by Unwin in Minutes of the Institution of Mechanical Engineers, vol. 53, and there is a more complete discussion in a book on centrifugal pumps by C. H. Innes.

Innes deals with various cases, discusses the losses at exit due to proper and improper design of the volute, and determines the best velocity in the latter. He further deals with the diffuser

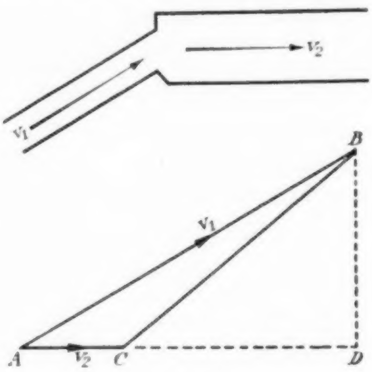

FIG. 5

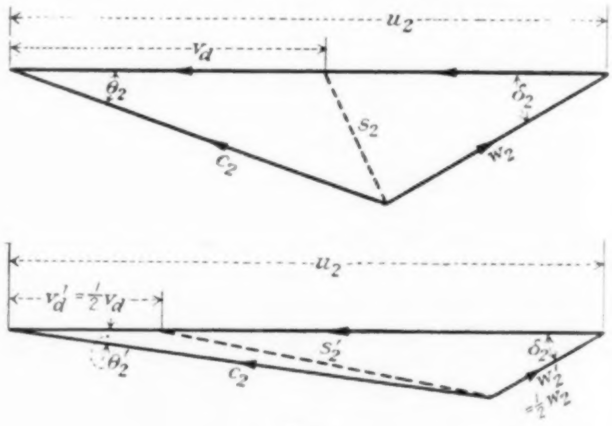

FIG. 6

or radial space frequently left between the rim of the impeller and the inside of the volute in the older pumps.

The author states that the friction losses are proportional to the square of the discharge. This statement is rather questionable when one considers the range of discharges with which the author deals. For small ranges of velocity a coefficient $c$ may be determined so that $h_f = cQ^2$, but such a law is far from true if there is much variation in the discharge. For example, in a 12-in. pipe the Hazen and Williams tables give the loss per 1000 ft. of old pipe, with a velocity of 1.97 ft. per sec., as 2.10 ft. and for a velocity of 10.84 ft. per sec. the loss is 49.4 ft.; the value of $h_f/v^2$ being 0.54 for the first case and 0.42 for the second case, a difference too great to neglect.

The expression for the loss of head due to shock as given in Equation [7] appears to the writer to be inaccurate. It has

[2] Professor of Mechanical Engineering, University of Toronto, Toronto, Ont. Mem. A.S.M.E.

been established as a general theorem that when water with velocity $v_1$ in a small pipe passes abruptly into a larger pipe where the velocity is $v_2$, the two pipes being in line, the loss of head is proportional to $(v_1 - v_2)^2$. In the case of pipes not in line as shown in Fig. 5, the loss is proportional to the vector difference between $v_1$ and $v_2$. Thus in the same figure $AB = v_1$, $AC = v_2$ and the loss of head is proportional to $(BC)^2$, or to the vector difference $(v_1 - v_2)^2$. The author assumes the loss of head due to shock to be proportional to $(AD)^2 - (AC)^2$ where $AD$ is the projection of $v_1$ on the direction of $v_2$. Regardless of which method is adopted, the coefficient $k_s$ cannot be regarded as constant. In King's "Handbook of Hydraulics" a table is given of values of the corresponding coefficient when the pipes

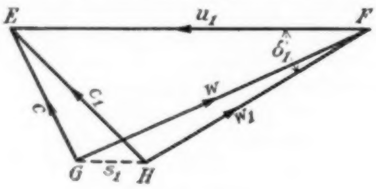

Fig. 7

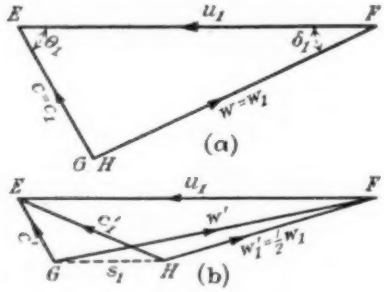

Fig. 8

are in line, which shows a variation of about 15 per cent when the velocity varies from 5 ft. per sec. to 40 ft. per sec.

Throughout the paper the author assumes constant speed, and the velocity triangles at exit from the impeller for two discharges, one equal to half of the other, are given in Fig. 6, the shock velocity being indicated by the letter $s_2$ and the loss due to shock being proportional to $s_2^2/2g$. It is quite possible to include an expression for $s_2^2/2g$ in the general pump theory which the author has given, although the resulting expression becomes somewhat cumbersome.

While the author has dealt with shock loss at exit from the impeller he has neglected entirely the corresponding loss at entry. The entry conditions are represented in Fig. 7 by the two triangles $EFG$ and $EFH$, the former representing the conditions just before entry and the latter the conditions just after entry. If the vanes are thin at this point, it is quite correct to draw $GH$ parallel to $EF$, but there is much uncertainty about the direction of $EG$, as the amount of whirl in the suction pipe is unknown. The letters are the same as the author's, and in this case the shock loss depends on the length of the line $GH = s_1$ and is proportional to $s_1^2/2g$.

If the designer knew the direction of $GE$ he would naturally make $G$ and $H$ coincide for the best efficiency, and this could be done for one discharge, but for all other discharges, at the same speed, $s_1$ is not zero. In Fig. 8 (*a*) shows the conditions for best efficiency and (*b*) the conditions for half the discharge corresponding to (*a*).

To make the theory complete, therefore, the two shock losses and the friction loss should be included, and as these are to be multiplied by coefficients which vary with the discharge, it would appear to be doubtful whether the analysis made by the author is reliable and can be made to furnish the information he desires. The author is, however, to be commended for returning to the early principles and bringing forward again the fundamental ideas on which the design of centrifugal pumps is based.

Some years ago the writer made a careful study of the same problem, introducing the expressions for the shock losses $s_1$ and $s_2$ mentioned in his discussion, and he found that the equation for the pump could be written in the form

$$AQ^2 + Bu_2Q + Cu_2^2 + 2gH = 0$$

where $A$ depends on the friction in the pump and also on the dimensions and angles, and $B$ and $C$ depend on the dimensions and angles only. If this equation is written so as to apply to a constant speed of operation,

$$AQ^2 + B'Q + C' + 2gH = 0$$

in which equation $H$ is the head against which the pump works. If the dimensions of the pump are available $B'$ and $C'$ may be readily determined, and the value of $A$ may be computed from different values of $Q$. Since $A$ includes the friction losses the latter may be determined.

The writer feels, however, that until there is greater certainty about the entry conditions and the action of the water in the impeller, these calculations cannot yield numerical results of much practical value.

The Author. Professor Angus, introducing an equation $AQ^2 + B'Q + C' + 2gH = 0$, claims that $AQ^2$ is the friction loss. This is not correct since $AQ^2$ includes part of the shock loss, which can be seen when following the derivation of Equation [21]. Consequently, the computed value of $A$ will be of no value. Moreover Professor Angus states that: "If the dimensions of a pump are available, $B'$ and $C'$ may be readily determined, and the value of $A$ may be computed from different values of $Q$." This statement is not correct since the actual angles which the water follows, as has been pointed out in the paper, are different from the casting angles of the impeller. For this very reason we have so much controversy about the validity of the different theories of the centrifugal pump. For the very same reason the author's method was introduced to avoid the use of the physical dimensions and angles which may lead, as every one who has dealt with centrifugal pumps knows, to preposterous results.

The shock loss at entrance due to thickness of the blades was not considered because the blades at the inlet of the impeller are usually sharpened and this loss becomes negligible. Innes, to whom Professor Angus refers, in "Centrifugal Pumps and Turbines," page 206, discussing Professor Unwin's analysis, says: "As he (Unwin) gives no vane thickness, it is probable he neglects that."

Another type of shock loss at entry is due to sudden change in direction of the absolute velocity and, as shown on page 193 of Innes' work, is equal to

$$h_s = \frac{c_{u1}^2}{2g}$$

This loss due to abrupt change of velocity would take place if directing vanes extending clear to the impeller tips were used. But modern practice to the author's knowledge no longer employs them.

Since water is set in rotation in the suction pipe there is no abrupt change in velocity for a relatively small discharge. For greater flows the rotation decreases and a certain amount of

loss at entrance may take place. But this, according to Daugherty's "Centrifugal Pumps," page 65, "does not seem to be of sufficient magnitude."

Hence the whole question of shock loss at the entry does not seem to be of great importance, especially as these relatively small losses if present will be included in the loss terms of Equation [15].

The treatment of the shock loss at the outlet of the impeller as presented by the author may be found in LeConte's "Hydraulics," Daugherty's "Centrifugal Pumps," and other treatises.

Water leaves the impeller with an absolute velocity $c_2$ which may be represented by two components, $c_{u2}$ (projection on the periphery) and $cr_2$ (radial component), and the expression for shock may be written as follows:

$$\frac{(c_{u2} - v_d)^2}{2g} + \frac{c_{r2}{}^2}{2g}$$

that is, the tangential component follows the law of sudden enlargement (difference in velocities squared) and the normal

From the principle of dynamic similarity we have for friction drop in circular pipes,

$$h_f = \frac{L}{d}\frac{v^2}{2g}\phi\left(\frac{vd}{\nu}\right) \qquad [30]$$

For streamline flow $\frac{vd}{\nu} < 2000$ and Equation [30] becomes

$$h_f = \frac{64}{2g}\frac{L}{d^2}v\nu \qquad [31]$$

For turbulent flow $\frac{vd}{\nu} > 3000$ Dr. Lee gives the following expression for the Stanton-Pannell curve:

$$\phi\left(\frac{vd}{\nu}\right) = 8\left[0.0765\left(\frac{\nu}{vd}\right)^{0.35} - 0.0009\right]$$

which substituted in Equation [30] gives

$$h_f = 8\left[0.0765\left(\frac{\nu}{vd}\right)^{0.35} - 0.0009\right]\frac{v^2}{2g}\frac{L}{d} \qquad [32]$$

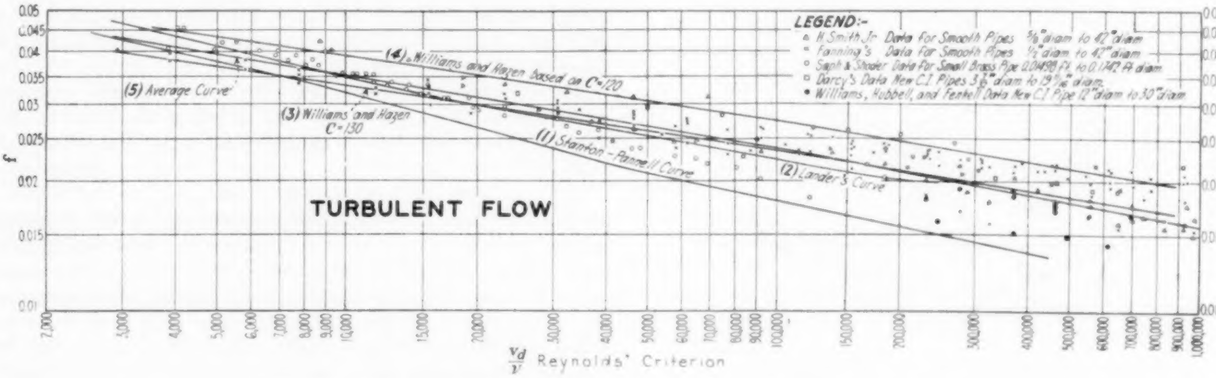

FIG. 9 RELATION BETWEEN $f$ AND $vd/\nu$ BASED ON EXPERIMENTAL DATA

component is wasted. The author when developing the expression for shock losses omitted the term $c_{r2}{}^2/2g$ purposely, since it appeared automatically in the friction term $CQ^2$ which included all losses following the law of variation of square of the velocity.

The table in King's "Handbook on Hydraulics" to which Professor Angus refers is based on experiments by H. W. Archer conducted in the hydraulic laboratory of the University of California. Professor LeConte of the same institution states in "Hydraulics," page 98: "Mr. H. W. Archer found that

$$h_s = 1.098\,\frac{(v_1 - v_2)^{1.919}}{2g}$$

though many experiments by the writer (LeConte) particularly at high velocities agree almost exactly with equation

$$h_s = \frac{(v_1 - v_2)^2}{2g},"$$

and since $K = I$, LeConte on page 99 states: "When a sudden enlargement exists in a pipe line the loss can be entered the energy equation by means of the expression

$$\frac{(v_1 - v_2)^2}{2g}$$

without the use of a coefficient $K$."

In general, in the case of a centrifugal-pump coefficient, $K$ appears to be less than unity, depending on the design of the pump in question.

where $d$ and $L$ are in feet, $v$ in feet per second, and $\nu$ is the kinematic viscosity in foot-poundal-second units.

It was noticed by the author that the values of $f$ — $(vd/\nu)$ as given by the Stanton-Pannell curve are somewhat low when used for commercially smooth pipes, and he therefore plotted values of $f$ against $vd/\nu$ for the turbulent flow from the data of various experimenters (Fig. 9), and drew his own average curve which satisfied an equation of the form:

$$\phi\left[\frac{vd}{\nu}\right] = \frac{0.167}{\left(\frac{vd}{\nu}\right)^{0.170}}$$

Substituting this in Equation [30],

$$h_f = 0.167\,\nu^{0.170}\,\frac{L}{d^{1.170}}\,\frac{v^{1.830}}{2g} \qquad [33]$$

This equation holds for any liquid flowing in a straight, commercially smooth circular pipe, and it may be noticed that no variable coefficient is introduced, since the coefficient and exponent are constant for any one type of surface.

The effect of roughness or curvature of the conduit, as indicated by various experiments, changes the slope of the $f$ — $vd/\nu$ curve, and consequently the method employed by Williams and Hazen in their tables in increasing the coefficient of friction to take care of roughness without the increase of the exponent, is incorrect.

Stanton, Gibson, Durand and others show that the roughness of a conduit increases the exponent $n$ of the Reynolds' formula

$$h_f = K \frac{v^n \nu^{2-n}}{d^{3-n}} L$$

Hence the case of the centrifugal pump with a revolving impeller having curved vanes and a volute casing could be approximated to that of a rough pipe, and the use of an exponent 2 with a constant coefficient similar to the Reynolds' equation was justified in opinion of the author.

Even if the exponent were less than 2 it would be higher than that in Williams and Hazen's formula, and the variation would be much smaller than claimed by Professor Angus.

On the other hand, assuming according to Professor Angus a 10 per cent variation in the coefficient of friction for half of the rated capacity, the friction loss for the above example (Table 2) at 300 gal. per min. would be $1.9 \times 0.90 = 1.71$, and the corresponding shock loss would be $16.80 + (0.10 \times 1.9) = 16.99$, a difference which could hardly be detected when plotted. The capacity on the right side of the point of maximum efficiency seldom extends farther than 50 to 75 per cent of the rated one, and consequently the variation would be negligible and in general much smaller than claimed by Professor Angus.

The real difficulties actually experienced by the author were due to excessive leakage and to "cut-off" phenomena, and he expected that among the discussions submitted there would be some comments on these points.

The leakage between the impeller and casing wear rings, if not excessive, can be taken care of by using two approximations and by moving the point of maximum hydraulic efficiency somewhat to the left from the point of maximum pump efficiency. If the results are still inconsistent, the influence of the short-circuit losses makes the analysis impossible unless the amount of leakage can be estimated.

By "cut-off" is meant a sudden drop in head, efficiency, and usually horsepower, which takes place when the inlet of the impeller becomes too small for a given flow and the pump becomes choked. No matter how wide the valve on the discharge of the pump is open, the capacity stays constant. It is evident that the equation of a parabola in the neighborhood of the "cut-off point" will not hold as a different law enters, and these points should be disregarded when determining the numerical values of Equation [21].

In conclusion, the author must state that this method of determining losses has been of great assistance in his practice. It has consistently indicated the correctly designed pumps and enabled him to reason out the cause of failure of pumps which otherwise could probably never be determined.

# A Method of Analyzing the Performance Curves of Centrifugal Pumps

## Development of Analytical and Graphical Methods of Determining Correction Factors from Test Curves for Use in Bringing Theoretical Pump Equations into Harmony with Practice

By JOSEPH LICHTENSTEIN,[1] ELIZABETH, N. J.

CENTRIFUGAL-PUMP practice still bases its calculations on the one-dimensional theory, which assumes a frictionless fluid flowing through an impeller with an infinite number of blades. It is evident that the results of this theory cannot well conform with actual practice where the number of blades is small, and where friction and a turbulent flow of water are encountered. Attempts to introduce a theory better adapted to the actual pump design have been made. Professor Lorenz has developed a two-dimensional theory (Neue Theorie and Berechnung der Schaufelrader), and Professor Prasil of Zurich has published a three-dimensional theory (Ueber Flüssigkeitsbewegungen in Rotationshohlraumen, *Schweizerische Bauzeitung*, 1923).

The pump designer rarely uses these theories. Not only because they are more complicated and not so general as the classical theory, being based on certain profiles which would limit the engineer in his designs, but especially because they are also based on a frictionless, non-turbulent flow, a supposition far from reality. The results obtained by employing these theories would therefore not be in correspondence with actual practice. It is therefore best to keep to the simple and most general, classical, one-dimensional theory, and to use it more as a guide indicating the general laws by which centrifugal pumps are governed, and with the understanding that its numerical results will have to be corrected by factors determined by means of actual experiences and tests. It is the deduction of these factors which is the task of this paper. Ordinarily the pump designer does not have the opportunity of measuring these factors directly, and besides, direct measurement, if not impossible, is at least very difficult. It will therefore be necessary to find an indirect method, using tests with which every pump manufacturer is familiar. These tests are the ordinary performance curves, capacity-head and brake-horsepower curves for constant speed.

### Correction Factors

It is also necessary before proceeding to decide what kind of factors are to be used in order to bring in correspondence theory and practice. Two values can always be brought into equality by multiplying one with a numerical correction factor. What the centrifugal-pump designer needs is a set of factors which are general and independent of the special design of pumps. This can only be the case if each factor is not merely a numerical value, but has a real physical meaning expressing the real reason for the difference between theory and practice. In the present study the author will use the following five correction factors which are to be deduced from the ordinary performance curves.

1 *Hydraulic Efficiency* is the ratio between the effective head and the total created head of the impeller. If we wish this hydraulic efficiency to be a physical reality, it is necessary that our theory shall really indicate the total created head of the actual pump. But we know that the equation of the total head in the one-dimensional theory indicates a far greater head than the actual pump creates. We shall therefore have to change the classical theory and introduce into it those physical factors which are the reason for the lesser action of the real pump. These factors are as follows:

2 *Real Angle of Water Leaving Blades at Exit.* Centrifugal-pump designers have long known that in the actual pump the water does not leave the blades tangentially, as assumed in the one-dimensional theory, but at an angle always smaller than that of the blades. The author will not discuss here the probable reasons for this fact. Possibly the principle of least resistance plays a certain role here. But whatever reasons may be involved we must take this fact into consideration. It is one of the material reasons for the deviation between theory and practice, and a knowledge of the water angle for every given blade angle is of great importance for the centrifugal-pump designer. By means of the method about to be described, this leaving angle of the water may be determined from ordinary pump performance curves.

3 *Whirl Component at Exit.* This is a physical factor taking into consideration the definite number of blades in the real pump rather than the infinite number of blades assumed in the classical theory. It has been introduced by various authors, especially in the hydrodynamic studies of Kucharski in his Movements of a Frictionless Fluid, Munich and Berlin, 1918, and Movements in the Rotating Channel, in *Zeitschrift fur das Gesamte Turbinenwesen*, 1917, The Steam Turbine, by Stodola, fifth edition, and The Centrifugal Pump, by Pfleiderer, Berlin, 1924, in which the idea has found a special application to centrifugal pumps. To explain the idea briefly, a centrifugal pump with a small number of blades can only transfer energy to the water if there is a difference of pressure between the acting and non-acting sides of the blades. This is only possible if the velocities on the acting side of the blade are smaller than on the opposite side. For the main flow of water through the impeller this is not possible if the blade thickness is assumed to be negligible. It is therefore necessary to combine with this main flow another flow of water rotating within the blades and in a direction opposite to the rotation of the impeller (see Fig. 1). This is the whirl flow. On the acting side of the blades this whirl flows counter to the main flow, thus reducing the resultant velocity, while on the non-acting side the opposite is the case.

At the periphery of the impeller the direction of the whirl is opposite to the rotation and therefore its velocity is opposite to the component of the absolute velocity in the tangential direction. This component of the absolute velocity is therefore reduced by the whirl component, as is also in consequence the moment given to the water by the blades. It is this whirl component which will have to be deduced from tests. The influence of this whirl component is not as great as it seems to appear in the studies of the above-mentioned authors, for the

[1] Bethlehem Shipbuilding Corporation. Mem. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of The American Society of Mechanical Engineers. First presented at a meeting of the Metropolitan Section, New York, March 9, 1927.

reason that these authors do not take in consideration the difference between the leaving angle of the water and the blade angle. They therefore introduce into this correction factor the influence of both, which makes the whirl component appear larger than it is.

4 *Rotation Component at Entrance.* The classical theory does not neglect this factor, but practice generally does in assuming a "normal" entrance, the absolute entrance velocity

FIG. 1

being taken normal to the circumferential velocity, in order to simplify the equations. But as an existing rotation component at the entrance would diminish the total created head, we cannot neglect it. Such a rotation of the water probably exists already in the suction pipe of the pump and the contact of the water with the rotating parts, pump shaft, and hub of the impeller will tend to increase this component. At least we shall introduce this rotation component in our equations, and the analysis of given tests will show if such a rotation exists and to what extent.

5 *Case Factor.* The factors mentioned in 1, 2, 3, and 4 are correction factors for the impeller alone. But the impeller alone does not determine a pump for given conditions of capacity and head at the point of highest efficiency. It is the case or the volute which determines this and it will be shown later how mathematically the volute and impeller are connected together for given conditions of capacity and head. For certain conditions the case is not arbitrary but theoretically determined, and it is necessary to introduce a case factor to bring in accordance the theoretical calculation of the case with actual experience. The definition of this case factor will be given later in the paper.

The knowledge of factors 1 to 5 for a series of pumps will enable the pump designer to calculate a pump for any condition with a high degree of accuracy and to answer any questions which may arise in the pump practice, such as changing the impeller in a given pump, changing the volute for a given impeller, or turning down the blades of a given pump.

It is now in order to develop the equations on which the analysis will be based. The following abbreviations will be used.

$H$ = total head created by impeller
$h$ = actual head measured.
$u_1$ = peripheral velocity at entrance of impeller
$u_2$ = peripheral velocity at exit
$C_1$ = absolute velocity at entrance
$C_2$ = absolute velocity at exit
$C_{u1}$ = projection of absolute velocity on $u_1$
$C_{u2}$ = projection of absolute velocity on $u_2$
$C_{r1}$ = radial component of absolute velocity at entrance
$C_{r2}$ = radial component of absolute velocity at exit
$\alpha$ = angle between absolute velocity and $u$
$\beta$ = angle between relative velocity and $u$
$\gamma$ = specific gravity of the liquid
$g$ = acceleration of gravity.

### THE EQUATION OF THE TOTAL HEAD

The equation of the total head in the classical one-dimensional theory is

$$H = \frac{1}{g}(u_2C_{u2} - u_1C_{u1}) \dots\dots\dots\dots\dots [1]$$

Figs. 2 and 3 show the exit and entrance diagrams representing Equation [1]. Generally it is assumed that $\alpha_1$ = 90 deg. or $C_{u1} = 0$, whence, from Fig. 2,

$$\frac{C_{r2}}{u_2 - C_{u2}} = \tan \beta_2$$

or

$$C_{u2} = u_2\left(1 - \frac{C_{r2}}{u_2 \tan \beta_2}\right)$$

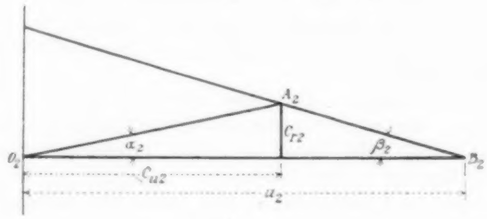

FIG. 2

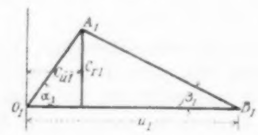

FIG. 3

and

$$H = \frac{u_2^2}{g}\left(1 - \frac{C_{r2}}{u_2 \tan \beta_2}\right) \dots\dots\dots\dots [1']$$

$C_{r2}$ represents the capacity, as the capacity only differs from $C_{r2}$ by a constant—the exit section of the impeller. Assuming that for various capacities or various diagrams $\beta_2$ remains constant, it follows from Equation [1] that the total-head capacity characteristic is a straight line.

### ASSUMPTION

*The only assumption made in this connection is that in an actual pump the total-head-capacity characteristic is also a straight line.* This assumption is well based on experience and on tests of various types of centrifugal pumps. Taking now into consideration $C_{u1}$ and introducing in the exit diagram the whirl component $u_w$, Fig. 4 results. Here $O_2B_2C_2$ is the theoretical triangle for an infinite number of blades. $A_2C_2 = u_w$ is the whirl component, and $O_2A_2B_2$ the real triangle. The whirl deviates the relative velocity opposite to the rotation, and decreases the component of the absolute velocity by $u_w$. $A_2C_2$ is parallel to $u_2$ because the capacity and therefore $C_{r2}$ is not changed by the whirl component. Fig. 5, $O_1A_1B_1$, is the entrance diagram and the initial equation for the total head is again

$$H = \frac{1}{g}(u_2C_{u2} - u_1C_{u1}) \dots\dots\dots\dots\dots [1]$$

where $C_{w2}$ represents the component of the absolute velocity of the *real* pump, and the component is smaller compared to the theoretical one by $u_w$.

According to the assumption made above, Equation [1] for various capacities must be a linear function. This will be the case if the points $A_1$ and $A_2$ of the diagrams, by varying $C_r$ will describe themselves straight lines, because then $C_{r1}$ will be a linear function of $C_{u1}$, and $C_{r2}$ a linear function of $C_{u2}$ and the connection of both by Equation [1], a linear function itself, will remain linear. This condition of $A_1$ and $A_2$ describing straight lines is surely sufficient as it would be highly

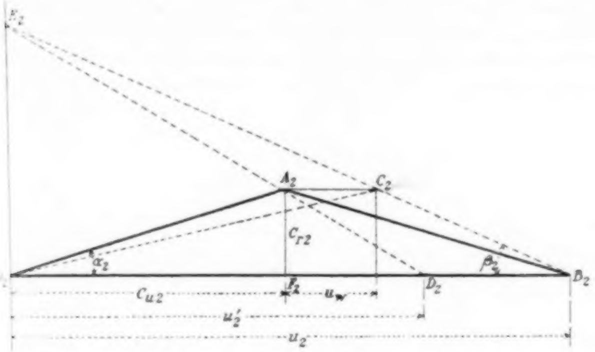

Fig. 4

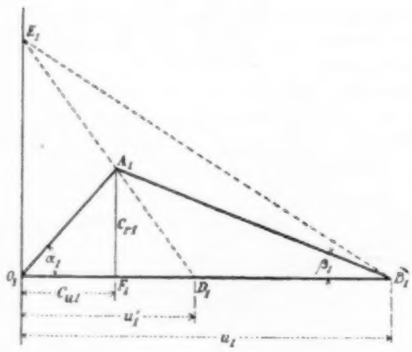

Fig. 5

improbable that $A_1$ and $A_2$ would describe curves symmetrical to a straight line so that their sum would be a liner function.

Another consideration which fixes the straight lines described by $A_1$ and $A_2$ is the point of the characteristic where the total head is zero. For this case we have a purely radial flow through the impeller without transfer of energy from the blades to the water. The whirl at the exit must, therefore, be zero as also are $C_{u1}$ and $C_{u2}$. It follows that for this point of $H = 0$, the exit diagram (see Fig. 4) must be $O_2E_2B_2$, and therefore, the straight line described by $A_2$ must intersect the axis of ordinates in $E_2$. The entrance diagram for this point is $O_1B_1E_1$ and the straight line described by $A_1$ must intersect the axis in $E_1$.

It is now possible in our system of coordinates (see Figs. 4 and 5) to develop the equations for the straight lines described by $A_1$ and $A_2$.

In the exit diagram, Fig. 4, the straight line of $A_2$ starting from $E_2$ intersects the $u_2$ axis in $D_2$. Call $O_2D_2 = u_2'$ and use this value as the unknown representing the whirl, for, knowing $u_2'$, we know the whirl component $u_w$ in every diagram. From the similar triangles $A_2F_2D_2$ and $O_2D_2E_2$, it is seen that

$$\frac{O_2E_2}{C_{r2}} = \frac{u_2'}{u_2' - C_{u2}}$$

$$O_2E_2 = u_2 \tan \beta_2$$

therefore,

$$C_{u2} = u_2' \left(1 - \frac{C_{r2}}{u_2 \tan \beta_2}\right) \qquad [2]$$

In the entrance diagram, Fig. 5, the radial velocities $C_{r1}$ and $C_{r2}$ are connected together by the equation of continuity

$$C_{r1}F_1 = C_{r2}F_2$$

where

$F_1$ = section at entrance of impeller
$F_2$ = section at exit of impeller.

For the point $H = 0$ the radial velocity at the exit is

$$C_{r2(\text{ex.})} = O_2E_2 = u_2 \tan \beta_2$$

and at the entrance

$$C_{r1(\text{ent.})} = O_1E_1 = u_2 \tan \beta_2 \frac{F_2}{F_1}$$

The straight line followed by $A_1$ intersects the $u_1$ axis in $D_1$ and $O_1D_1 = u_1'$ will be taken as the unknown characterizing the entrance rotation, for, knowing $u_1$, $C_{u1}$ is known for every diagram.

It follows from the similar triangles $A_1F_1D_1$ and $O_1E_1D_1$ that

$$\frac{C_{r1}}{O_1E_1} = \frac{u_1' - C_{u1}'}{u_1'}$$

$$\frac{C_{r2}\left(\dfrac{F_2}{F_1}\right)}{u_2 \tan \beta_2 \left(\dfrac{F_2}{F_1}\right)} = \frac{u_1' - C_{u1}}{u_1'}$$

or

$$C_{u1} = u_1' \left(1 - \frac{C_{r2}}{u_2 \tan \beta_2}\right) \qquad [3]$$

Substituting these values in Equation [1] equation of the total head reads;

$$H = \frac{(u_2u_2' - u_1u_1')}{g} \left(1 - \frac{Cr_2}{u_2 \tan \beta_2}\right) \qquad [4]$$

$$\text{For } C_{r2} = 0, \quad H = \frac{u_2u_2' - u_1'u_1}{g}$$

$$\text{For } H = 0, \quad C_{r2} = u_2 \tan \beta_2$$

In analyzing a test, $u_2'$, $u_1'$, and $\tan \beta_2$ are to be considered as unknown and have to be determined by other conditions which it is the author's purpose to develop.

### The Hydraulic Efficiency

The hydraulic efficiency is the ratio between the measured head $h$ and total head $H$.

$$\eta_h = \frac{h}{H}$$

In a given test $h$ is a given function of $C_r$ and $H$ is determined by Equation [4]. The hydraulic efficiency is therefore a function of $C_r$ also, and is a maximum when

$$\frac{d\eta_h}{dC_r} = 0$$

$$\frac{d\eta_h}{dC_r} = \frac{H\dfrac{dh}{dC_r} - h\dfrac{dH}{dC_r}}{H^2}$$

and it follows for the maximum condition that

$$H \frac{dh}{dC_r} - h \frac{dH}{dC_r} = 0$$

$$\frac{1}{H} \cdot \frac{dH}{dC_r} = \frac{1}{h} \cdot \frac{dh}{dC_r}$$

$dH/dC_r$ is the tangent of the angle which the total-head straight line forms with the positive $C_r$ axis, Fig. 7, while $dh/dC_r$ is the tangent of the angle which the tangent to the characteristic curve at the point of maximum hydraulic efficiency forms with the positive $C_r$ axis (Fig. 7). Therefore

$$\frac{dH}{dC_r} = -\tan\gamma' = -\frac{H}{AP}$$

$$\frac{dh}{dC_r} = -\tan\gamma = -\frac{h}{AP}$$

and

$$\frac{H}{H \cdot AP} = \frac{h}{h \cdot AP}$$

or

$$AP = AP$$

It is thus seen that *the tangent to the characteristic curve at the point of maximum hydraulic efficiency intersects the $C_r$ axis at the same point as the total-head straight line*, which point is $C_{r0} = u_2 \tan\beta_2$.

If by some other condition we determine the point $P$ we can project from $P$ the tangent to the characteristic curve and thus find the point of maximum hydraulic efficiency. In order to find this other condition, we shall have to use another curve obtainable from tests, namely, the brake-horsepower curve. Therefore, for the purpose of comparison, it will be necessary to develop the equation of the total hydraulic energy received by the water from the blades.

### The Total Hydraulic Energy

If in Equation [4] we multiply the total head by the capacity, we obtain the equation for the total hydraulic energy. It is desirable to express this energy in horsepower as it will have to be compared with the brake-horsepower curve. Calling the total energy $E_t$, then

$$E_t = c\gamma QH$$

where $c$ = constant for expressing the energy in hp.
$\gamma$ = specific gravity of liquid, and
$Q$ = capacity per unit of time.

Taking $Q = F_2 \times C_{r2}$ and inserting the value of $H$ from Equation [4] in the above expression will give

$$E_t = c \cdot \gamma F_2 \left(\frac{u_2u_2' - u_1u_1'}{g}\right)\left(C_r - \frac{C_r^2}{u_2 \tan\beta_2}\right) \quad \ldots [5]$$

Equation [5] is a parabola; $E_t = 0$ where $C_r = 0$ and also where $C_r = u_2 \tan\beta_2$. This parabola intersects the $C_r$ axis at the same point as the total-head straight line.

The total-energy curve has its maximum when

$$\frac{dE_t}{dC_r} = 0$$

$$\frac{dE_t}{dC_r} = c\gamma F_2 \left(\frac{u_2u_2' - u_1u_1'}{g}\right)\left(1 - \frac{2C_r}{u_2 \tan\beta_2}\right)$$

It therefore follows that the maximum is reached when

$$C_r = \frac{u_2 \tan\beta_2}{2} \quad \ldots\ldots\ldots\ldots [6]$$

The maximum of the total-energy curve is reached at a capacity which is half the capacity at which the total created head is zero. This fact is important and will be made use of later.

### Comparison Between Brake-Horsepower Curve and Total-Hydraulic-Energy Curve

The brake horsepower is the energy input into the pump. It has to cover the total hydraulic energy created and the friction losses of a mechanical nature such as the disk friction and the friction in the stuffing boxes and bearings, leakage for the moment being neglected. The leakage in a centrifugal pump is usually

Fig. 6

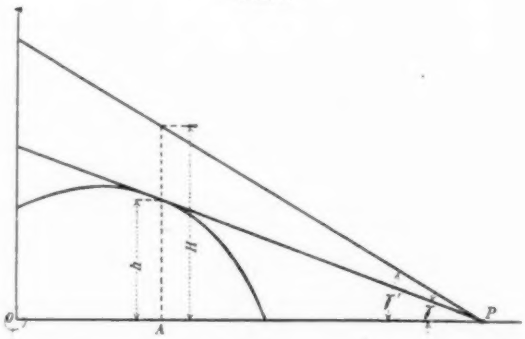

Fig. 7

very small. In the first attempt at analyzing a test curve the leakage cannot be considered as we do not yet know the diagrams of the pump and so are not able to calculate the static pressure at the exit of the impeller, which determines the leakage. We must, therefore determine our diagrams first without considering leakage. With these diagrams we can determine the leakage and in a second attempt can analyze our test curves, taking the leakage into consideration, as will be shown later.

Letting $E_B$ = brake-horsepower input into the pump
$E_t$ = total hydraulic energy, and
$E_R$ = sum of mechanical exterior friction losses,

follows from the above statement that

$$E_B = E_t + E_R \quad \ldots\ldots\ldots\ldots [7]$$

in which $E_B$ is a function of $C_r$, given by test; $E_t$ is a function of $C_r$, given by Equation [5]; and $E_R$ is constant and independent of $C_r$.

The exterior mechanical friction losses are dependent only upon the speed, which in the tests is kept constant. The friction

on the side walls of the impeller, in the bearings and stuffing boxes can surely have no relation whatever to the capacity of the pump.

If we now differentiate Equation [7] we obtain

$$\frac{dE_B}{dC_r} = \frac{dE_t}{dC_r} \qquad [8]$$

and we conclude from Equation [8] that

*For any point of capacity the tangent to the brake-horsepower curve and the tangent to the total-hydraulic-energy parabola are parallel.*

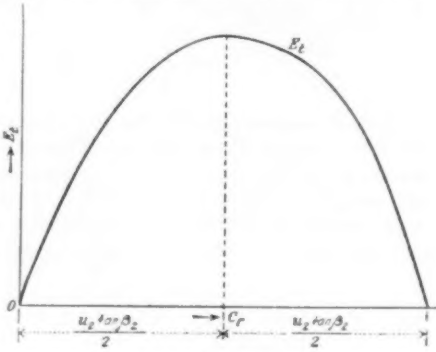

FIG. 8

Equation [8] holds only valuable for a limited range around the points of maximum hydraulic and total efficiencies. Where the capacities are small it is known that besides the main flow there is a secondary flow of the water which acquires energy that is not independent of the capacity. Therefore another element enters into Equation [7] that is dependent on the capacity and so Equation [8] loses its value. It is interesting to note that when we come to determine the parabola of the total hydraulic energy we shall be able at the same time to determine this range of secondary water movements in the impeller.

## THE TOTAL EFFICIENCY

The total efficiency is a known value, obtained by tests as a function of the capacity. But its maximum is sometimes difficult to determine exactly as the efficiency curve is often very flat at the maximum. It is, therefore, desirable to obtain a method by means of which this point of maximum efficiency can be determined with greater precision.

By definition, the total efficiency is

$$\eta_t = \frac{c\gamma Qh}{E_B}$$

$c\gamma Qh$ is the so-called water horsepower or the amount of energy in hp. which the water effectively possesses when leaving the pump.

Calling the water horsepower $E_W$, then

$$\eta_t = \frac{E_W}{E_B}$$

$E_W$ is a given function of the capacity. We can obtain this function graphically by multiplying at every point the capacity by the head of the characteristic curve at that point and by a constant to express the result in horsepower. $E_B$ is a given function of the capacity-b.hp. curve.

The maximum of $\eta_t$ is reached when $\frac{d\eta_t}{dC_r} = 0$

$$\frac{d\eta_t}{dC_r} = \frac{E_B \cdot \frac{dE_W}{dC_r} - E_W \frac{dE_B}{dC_r}}{E_B^2} = 0$$

It follows, therefore, that

$$\frac{1}{E_B} \times \frac{dE_B}{dC_r} = \frac{1}{E_W} \times \frac{dE_W}{dC_r}$$

Similarly as in the case of the hydraulic efficiency, the above equation states that:

*At the point of maximum total efficiency the tangent to the b.hp. curve and the tangent to the water-hp. curve intersect in a point lying on the $C_r$ axis.*

Knowledge of this fact will make it possible, in case of necessity, to determine more exactly the point of best total efficiency. See Fig. 9.

## GRAPHICAL DETERMINATION OF THE TOTAL-HYDRAULIC-ENERGY PARABOLA

Sufficient conditions have now been developed to make it possible to determine from the given test curves the parabola of the total hydraulic energy and in consequence the total-head straight line. The author will divide this problem into two parts.

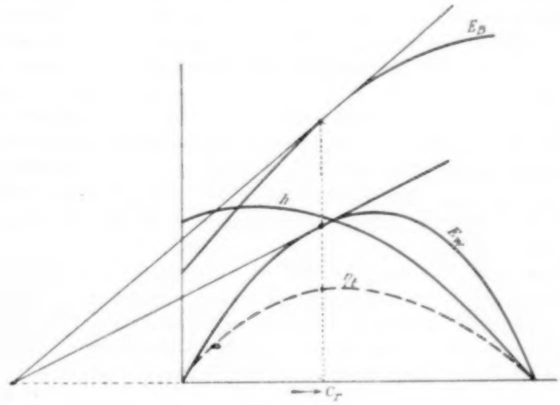

FIG. 9

(*a*) *The Brake-Horsepower Curve Has a Maximum.* In this case and in consequence of Equation [8] it is known that the parabola of the total hydraulic energy has its maximum at the same capacity as the b.hp. curve and intersects the axis at twice this capacity.

Calling the radial velocity at the point of the b.hp. maximum $C_{rm}$, then Equation [6] gives

$$C_{rm} = \frac{u_2 \tan \beta_2}{2}$$

$$\tan \beta_2 = \frac{2 \cdot C_{rm}}{u_2} \qquad [9]$$

*Equation [9] makes it possible to determine the real angle with which the water leaves the blades.*

Knowledge of the location of point $P$ allows now the drawing of a tangent to the given characteristic curve, and *the point where this tangent touches the curve is the point of maximum hydraulic efficiency.*

From the parabola of total hydraulic energy we know now the chord $OP$ and the $C_r$ at which the maximum is attained.

The parabola is completely determined if we add another condition due to Equation [8] when we choose the direction of

the tangent at another value of $C_r$ of the parabola. For this we may choose the tangent $m$-$m$ on the b.hp. curve at the point of highest total or hydraulic efficiency, to which the corresponding tangent of the parabola at the same value of $C_r$ is parallel. From the analytical geometry of the parabola we now recall the following statements (see Figs. 10 and 11).

1 A diameter $EQ$ of the parabola bisects all chords $OA$ which are parallel to the tangent $m'$-$m'$ at its end point $E$ so that $OB = BA$ (see Fig. 10). This statement allows us to obtain the point $A$ of our parabola if we draw $OA$ parallel to the tangent chosen on the b.hp. curve and make $OB = BA$.

2 To obtain other points of the parabola the construction given in Fig. 11 may be employed. Given a chord $OP$ of the parabola normal to the axis and a point $A$. Erect $PR$ and $AQ$ perpendicular to $OP$ and draw $OAR$ and $QR$. If we draw $A_1Q_1$ perpendicular to $OP$ and $Q_1R_1$ parallel to $QR$, then the line $OR_1$ will intersect the line $Q_1A_1$ in the point $A_1$ of the parabola.

From the parabola the total-head straight line may be found by dividing at any point of $E_t$ by a constant and $C_r$ as shown previously. The ratios between the characteristic curve and the total head $H$ gives the curve of hydraulic efficiencies and its maximum at the previously determined point. The difference between $E_B$ and $E_t$ at any point, for example, at the maximum total efficiency, gives the external friction losses. If we add to the total energy of the parabola this amount of friction losses, we obtain a curve which is the b.hp. curve at the maximum efficiencies. This curve deviates from the b.hp. curve obtained by test at the origin of the characteristic and the differences between the two curves gives the energy of the secondary movements in the impeller. The intersection of the straight line of the total head with the axis of ordinates gives us the value $(1/g)(u_2u_2' - u_1u_1')$.

*Analytical Solution.* Instead of constructing the parabola geometrically, we can of course calculate it analytically. Calling $C_{rm}$ the radial velocity at the point where the b.hp. curve has a maximum and $C_{rt}$ the radial velocity at the point of highest total efficiency, then Equation [5] below gives the parabola.

$$E_t = c\gamma F_2\left(\frac{u_2u_2' - u_1u_1'}{g}\right)\left(C_r - \frac{C_r^2}{u_2 \tan \beta_2}\right)$$

and

$$\frac{dE_t}{dC_r} = c\gamma F_2\left(\frac{u_2u_2' - u_1u_1'}{g}\right)\left(1 - \frac{2C_r}{u_2 \tan \beta}\right)$$

for $$C_r = C_{rm}, \quad \frac{dE_t}{dC_r} = 0, \quad \text{hence } \tan \beta_2 = \frac{2\,C_{rm}}{u_2}$$

for $$C_r = C_{rt}, \quad \frac{dE_t}{dC_r} = \tau$$

where $\tau$ is the slope of the b.hp. curve at the point of best efficiency

$$\tau = c\gamma F_2\left(\frac{u_2u_2' - u_1u_1'}{g}\right)\left(1 - \frac{2\,C_{rt}}{u_2 \cdot \dfrac{2C_{rm}}{u_2}}\right)$$

therefore

$$(u_2u_2' - u_1u_1') = \frac{g \cdot \tau}{c\gamma F_2}\,\frac{1}{\left(1 - \dfrac{C_{rt}}{C_{rm}}\right)}$$

and

$$E_t = \frac{\tau}{\left(1 - \dfrac{C_{rt}}{C_{rm}}\right)}\left(C_r - \frac{C_r^2}{C_{rm}}\right) \quad [10]$$

Equation [10] gives the parabola of the total hydraulic energy if $C_{rm}$, $C_{rt}$ and $\tau$ are known from the test.

From Equation [10] the equation of the total-head straight line $H$ may be derived:

$$H = \frac{E_t}{c \cdot \gamma F_2 \cdot C_r} = \frac{\tau}{c\gamma F_2\left(1 - \dfrac{C_{rt}}{C_{rm}}\right)}\left(1 - \frac{C_r}{2\,C_{rm}}\right) \quad [11]$$

also, for $C_r = 0$,

$$\frac{u_2u_2' - u_1u_1'}{g} = \frac{\tau}{c\gamma F_2\left(1 - \dfrac{C_{rt}}{C_{rm}}\right)} \quad [12]$$

(*b*) *The Brake-Horsepower Curve Has No Maximum.* In principle this case does not differ from the previous one. We used the knowledge of the direction of two tangents to the parabola and instead of employing the horizontal tangent as before we must employ in addition to the tangent at the point of maximum total efficiency, another tangent, as for example,

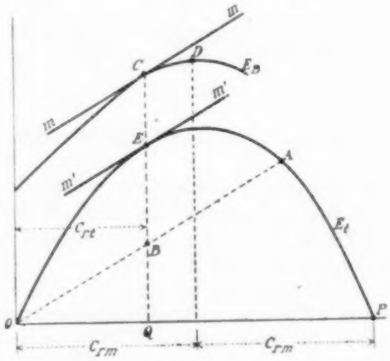

FIG. 10

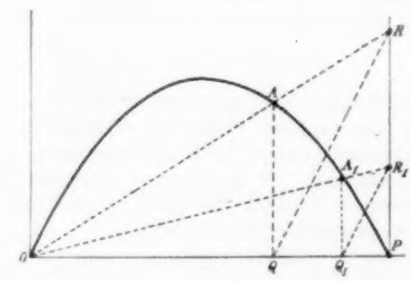

FIG. 11

at the point of maximum hydraulic efficiency. If these points are too close together, any other point on the b.hp. curve where the secondary movements have not influenced it as yet, may be used.

*Graphical Solution.* Knowledge of the directions of two tangents on the parabola makes it possible to determine two points of the parabola $A_1A_2$ as previously described. In order to find the intersection of the parabola with $C_r$ axis, use the construction indicated in Fig. 12. Make $Q_2B_2 = Q_1B_1$ and connect $A_1$ with $B_2$. The line $A_1B_2$ intersects the $C_r$ axis at the characteristic point $P$. Thus this problem is brought back to the graphical solution of the previous one.

*Analytical Solution.* Calling the radial velocities at the two points where the tangents are known $C_{rt}$ and $C_{rh}$ and $\tau_t$ and $\tau_h$ the tangents of the angles which these tangents respectively form with the positive $C_r$ axis, then the following conditions obtain:

For $C_r = C_{rt}$, $\dfrac{dE_t}{dC_r} = \tau_t$

for $C_r = C_{rh}$, $\dfrac{dE_t}{dC_r} = \tau_h$

$$\tau_t = c\gamma F_2 \left(\frac{u_2u_2' - u_1u_1'}{g}\right)\left(1 - \frac{2\,C_{rt}}{u_2 \tan \beta_2}\right)$$

$$\tau_h = c\gamma F_2 \left(\frac{u_2u_2' - u_1u_1'}{g}\right)\left(1 - \frac{2\,C_{rh}}{u_2 \tan \beta_2}\right)$$

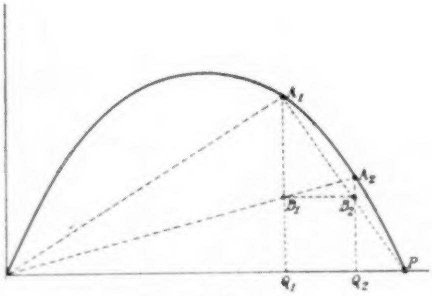

FIG. 12

$$\frac{\tau_t}{\tau_h} = \frac{1 - \dfrac{2\,C_{rt}}{u_2 \tan \beta_2}}{1 - \dfrac{2\,C_{rh}}{u_2 \tan \beta_2}}$$

from which

$$\tan \beta_2 = \frac{2\left(C_{rt} - \dfrac{\tau_t}{\tau_h}\,C_{rh}\right)}{\left(1 - \dfrac{\tau_t}{\tau_h}\right)u_2} \qquad [13]$$

Equation [13] gives the leaving angle of the water.

$$c\gamma F_2\left(\frac{u_2u_2' - u_1u_1'}{g}\right) = \frac{\tau_t}{1 - \dfrac{2\,C_{rt}}{u_2 \tan \beta_2}}$$

and $\tan \beta_2$ of Equation [13] gives

$$c\gamma F_2\left(\frac{u_2u_2' - u_1u_1'}{g}\right) = \frac{\tau_t}{1 - \dfrac{C_{rt}\left(1 - \dfrac{\tau_t}{\tau_h}\right)}{C_{rt} - \dfrac{\tau_t}{\tau_h}\,C_{rh}}}$$

$$E_t = \frac{\tau_t}{1 - \dfrac{C_{rt}\left(1 - \dfrac{\tau_t}{\tau_h}\right)}{C_{rt} - \dfrac{\tau_t}{\tau_h}\cdot C_{rh}}}\left[C_r - \frac{C_r^2\left(1 - \dfrac{\tau_t}{\tau_h}\right)}{2\left(C_{rt} - \dfrac{\tau_t}{\tau_h}\,C_{rh}\right)}\right] \qquad [14]$$

and the total-head straight line is given by:

$$H = \frac{E_t}{c\gamma F_2 C_r} = \frac{\tau_t}{c\gamma F_2}\left[\frac{1}{1 - \dfrac{C_{rt}\left(1 - \dfrac{\tau_t}{\tau_h}\right)}{C_{rt} - \dfrac{\tau_t}{\tau_h}\,C_{rh}}}\right]$$

$$\times \left[1 - \frac{C_r\left(1 - \dfrac{\tau_t}{\tau_h}\right)}{2\left(C_{rt} - \dfrac{\tau_t}{\tau_h}\,C_{rh}\right)}\right] \qquad [15]$$

Also

$$\frac{u_2u_2' - u_1u_1'}{g} = \frac{\tau_t}{c\;\gamma F_2}\left[\frac{1}{1 - \dfrac{C_{rt}\left(1 - \dfrac{\tau_t}{\tau_h}\right)}{C_{rt} - \dfrac{\tau_t}{\tau_h}\cdot C_{rh}}}\right] \qquad [16]$$

### DETERMINATIONS OF THE VALUES OF $u_1'$ AND $u_2'$

From the analysis so far developed we can obtain the value of the expression $u_2u_2' - u_1u_1'$, but as yet no method of separately determining $u_1'$ and $u_2'$ has been given. For this another condition is required and therefore the following assumption, which is well founded both theoretically and practically, will be made.

*Assumption.* At the point of maximum total efficiency the water enters the blades without shock; in other words, the water enters the blades tangentially at the angle $\beta_1$ which is known from the design of the pump. This determines $u_1'$ completely.

In laying out the entrance diagram (Fig. 13), $\beta_1$ is known and the radial velocity at the entrance for the point of maximum total efficiency is $C_{r1t}$, thus determining the triangle $OA_1B_1$ and $C_{u1}$. From the analysis $OE_1$ is known:

$$OE_1 = u_2 \tan \beta_2 \cdot \frac{F_2}{F_1}$$

Connecting $E_1$ with $A_1$ we obtain $D_1$ and $u_1'$, and from similar triangles we obtain

$$\frac{C_{r1t}}{u_2 \tan \beta_2 \dfrac{F_2}{F_1}} = \frac{u_1' - C_{u1}}{u_1'} = \frac{u_1' - \left(u_1 - \dfrac{C_{r1t}}{\tan \beta_1}\right)}{u_1'}$$

and

$$C_{r1t} = C_{rt}\,\frac{F_2}{F_1}$$

Where $C_{rt}$ is the radial velocity at exit,

$$u_1' = \frac{u_1 - \dfrac{C_{rt}\cdot F_2}{\tan \beta_1 F_1}}{1 - \dfrac{C_{rt}}{u_2 \tan \beta_2}} \qquad [17]$$

Knowing $u_1'$ from our analysis and $\dfrac{u_2u_2' - u_1u_1'}{g}$, the value of $u_2'$ is of course determined, and with it the exit diagram and $C_{u2}$ (see Fig. 14). We know from our analysis $\beta_2$, $u_2'$, and $C_{r2}$, the radial velocity at the point of maximum efficiency, and thus obtain $C_{u2}$ and the real whirl component $u_w$.

From similar triangles

$$\frac{u_w}{u_2 - u_2'} = \frac{u_2 \tan \beta_2 - C_{r2}}{u_2 \tan \beta_2}$$

$$u_w = (u_2 - u_2')\left(1 - \frac{C_{r2}}{u_2 \tan \beta_2}\right) \qquad [18]$$

and $C_{u2}$ is given by:

$$C_{u2} = u_2 - \frac{C_{r2}}{\tan \beta_2} - u_w$$

hence

$$C_{u2} = u_2' \left(1 - \frac{C_{r2}}{u_2 \tan \beta_2}\right) \quad \ldots\ldots\ldots\ldots [19]$$

At the beginning of the paper reference was made to The Centrifugal Pump, by C. Pfleiderer (Berlin, 1924, Julius Springer). In this work Herr Pfleiderer develops the following formula for the whirl component $u_x$:

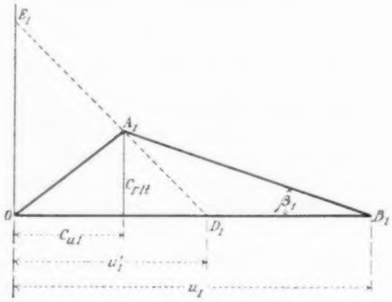

FIG. 13

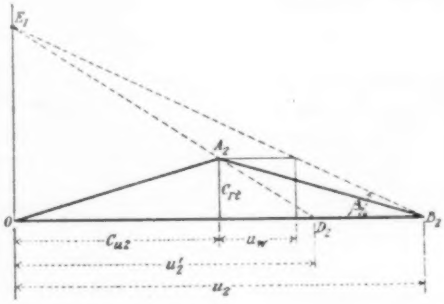

FIG. 14

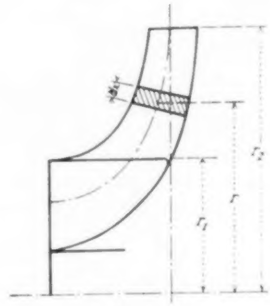

FIG. 15

$$u_w = \psi \frac{g r_2^2 H}{z S u_2}$$

where $\psi$ = a dimensionless constant
$z$ = number of blades
$r_2$ = impeller radius at exit, and
$S$ = static moment of average streamline in the impeller.

$$S = \int_{r_1}^{r_2} r dx \text{ (see Fig. 15)}$$

for $C_r = 0$, $H = \frac{u_2 u_2' - u_1 u_1'}{g}$ and $u_w = u_2 - u_2'$,

therefore

$$\psi = \left(\frac{zS}{r_2^2}\right)\left[\frac{u_2(u_2 - u_2')}{u_2 u_2' - u_1 u_1'}\right] \quad \ldots\ldots\ldots\ldots [20]$$

Equation [20] will enable us to deduce from our tests the value of $\psi$. Incidentally, it would be highly interesting to determine from a series of tests whether $\psi$ is a real constant independent of the design of the pump.

The analysis of the impeller being completed we are now able to take in consideration the leakage by calculating it from diagrams developed after known methods.[2] But, before proceeding we shall analyze a pump by the methods that have been developed.

## Graphical Analysis of a 10-In. Bethlehem Centrifugal Pump Tested at 1150 R.P.M.

Referring to Fig. 16, the characteristic curve $h$, the b.hp. curve $E_B$, and the total efficiency curve $\eta_t$ are obtained by test. The pump has the following dimensions:

| | |
|---|---|
| Exit diameter | $D_2 = 16^1/_2$ in. |
| Entrance diameter | $D_1 = 8^1/_2$ in. |
| Exit section | $F_2 = 0.509$ sq. ft. |
| Entrance section | $F_1 = 0.466$ sq. ft. |
| Exit angle of the blades | $\beta_2' = 20$ deg. |
| Entrance angle of the blades | $\beta_1 = 15$ deg.; $\tan \beta_1 = 0.2679$ |

[2] It is known from the theory of centrifugal pumps that the leakage varies with the capacity as a flat ellipse. We could calculate this ellipse and from that design the new characteristic curve, and repeat the whole analysis. However, the author will not go into the details of this correction as it would reveal nothing new.

$$u_2 = \frac{\pi \times 1.373 \times 1150}{60} = 82.7 \text{ ft. per sec.}$$

$$u_1 = \frac{8.5 \times 82.7}{16.5} = 42.55 \text{ ft. per sec.}$$

The b.hp. curve has a maximum at a capacity of 2500 gal. per min. = 5.54 cu. ft. per sec. The corresponding radial velocity at the exit is:

$$C_{rm} = \frac{5.54}{0.509} = 10.89 \text{ ft. per sec.}$$

From Equation [9] we therefore obtain the leaving angle of the water at exit.

$$\tan \beta_2 = \frac{2 \times 10.89}{82.7} = 0.263$$

This angle is approximately 14 deg. 45 min. as compared with the 20 deg. of the blades. The maximum hydraulic efficiency occurs at the capacity where a line from the characteristic point $P$ is tangent to the characteristic curve $h$. This capacity is 1940 gal. per min., whereas the maximum total efficiency occurs at the capacity 2000 gal. per min. With the line $m$-$m$ tangent to the b.hp. curve at the point of maximum total efficiency the parabola $E_i$ has been constructed according to the method previously described. The difference between this parabola and the b.hp. curve at the point of maximum total efficiency is 9 hp., which is the value of external friction losses. The horizontally shaded field between the parabola and the b.hp. curve indicates the range of secondary movements and the hp. needed at every capacity for these movements. The total-head straight line $H$ is obtained if one point is deduced from the parabola, as, for example, the point of maximum hydraulic efficiency. At this point $E_i$ = 51 hp., and therefore $H$ = $3960 \times 51/1940 = 104$ ft.

The head $h$ at this point = 94.5 ft., so that the maximum hydraulic efficiency is $\eta_h = 94.5/104 = 0.907$. The straight line intersects the axis of coordinates at a head of 170 ft., so that

$$\frac{u_2 u_2' - u_1 u_1'}{g} = 170 \text{ ft.}$$

The vertically shaded field between the total-head straight line $H$ and the characteristic curve $h$ gives the amount of the hydraulic losses, and the ratio between the two gives the hydraulic-efficiency curve.

The point of maximum total efficiency is at 2000 gal. per min.

= 4.43 cu. ft. per sec. The corresponding radial velocities at entrance and exit are:

$$C_{r2} = \frac{4.43}{0.509} = 8.71 \text{ ft. per sec.}$$

$$C_{r1} = \frac{4.43}{0.466} = 9.5 \text{ ft. per sec.}$$

For the entrance and exit diagrams,

$$OE_2 = u_2 \times \tan \beta_2 = 82.7 \times 0.263 = 21.8 \text{ ft. per sec.}$$

$$u_w = (82.7 - 72.3)\left(1 - \frac{8.71}{82.7 \times 0.263}\right) = 6.25 \text{ ft. per sec.}$$

and from Equation [19]

$$C_{u2} = 72.3\left(1 - \frac{8.71}{82.7 \times 0.263}\right) = 43.4 \text{ ft. per sec.}$$

Using these values, the entrance and exit diagram has been drawn as shown at the left in Fig. 16.

To calculate the constant $\psi$ of Equation [20] we note that the

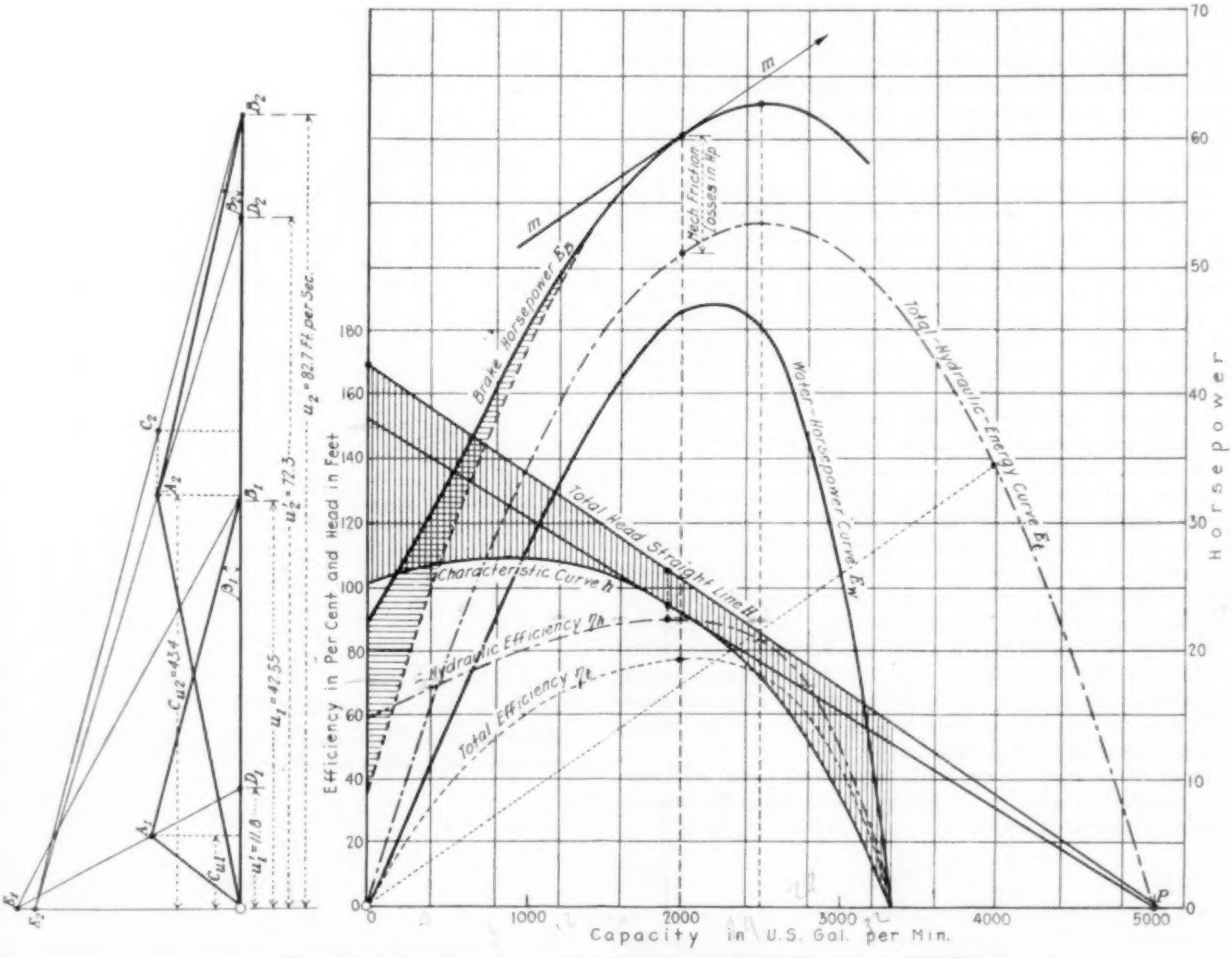

Fig. 16 Graphical Analysis of a 10-In. Centrifugal Pump Tested at 1150 R.P.M.

$$OE_1 = 21.8 \times \frac{0.509}{0.466} = 23.8 \text{ ft. per sec.}$$

and Equation [17] gives the following value of $u_1'$:

$$u_1' = \frac{42.55 - \dfrac{8.71 \times 0.509}{0.2679 \times 0.466}}{1 - \dfrac{8.71}{82.7 \times 0.263}} = 11.8 \text{ ft. per sec.}$$

$$u_2' = \frac{32.2 \times 170 + 11.8 \times 42.55}{82.7} = 72.3 \text{ ft. per sec.}$$

and the real whirl component as given by Equation [18] is

number of blades $z = 9$. The static moment of the average stream line

$$S = \int_{r_1}^{r_2} r dx = 0.17315 \text{ sq. ft.}$$

whence

$$\psi = \left(\frac{9 \times 0.17315}{0.4715}\right)\left[\frac{82.7\,(82.7 - 72.3)}{32.2 \times 170}\right] = 0.52$$

## Connection of Impeller and Casing

Having completed the study of the impeller, it is now necessary to study the second element of the centrifugal pump, the casing, and to develop the equations which connect the case to the impeller.

It has been shown that for a given impeller with given

speed the total-head straight-line characteristic can be completely determined without taking the casing surrounding it into consideration. It has also been shown that the real characteristic curve has its maximum hydraulic efficiency where the tangent drawn from the characteristic point $P$ touches the curve (see Fig. 17). This tangent $P$-$E$ to the characteristic curve is nothing else but the total-head straight line of the impeller for a hydraulic efficiency constant and equal to the maximum hydraulic efficiency of the characteristic curve. The hydraulic efficiency of the real characteristic varies. Any straight line from $P$ represents a total-head characteristic of the impeller for a certain constant hydraulic efficiency ranging from efficiencies of 100 per cent to zero. Such a straight line must intersect the real characteristic curve in the two points where the hydraulic efficiency corresponds to the value of this line. For the maximum hydraulic efficiency the corresponding straight line must be tangent to the characteristic curve, as there is only one point of the real characteristic which has this efficiency.

In enclosing a given impeller in different casings we know from experience that the characteristic curves are different and so are the capacity and head at which the maximum hydraulic efficiency occurs. But the value of this maximum hydraulic efficiency does not change over a wide range of different casings. It follows, therefore, from the considerations stated above that all these different characteristic curves must have the same straight line as a tangent but touching them at various points. This is a fact well proved by actual experience. The casing determines the point of the straight line at which the real characteristic will have its maximum hydraulic efficiency. It is quite evident that for the real pump the casing is of enormous influence and that for a given impeller different cases may create various shapes of characteristics and various points of capacity and head at which the hydraulic efficiency will be maximum. It is therefore necessary to develop the equations which will determine for a given impeller and case the capacity and head at which the hydraulic efficiency will be maximum.

For a given impeller rotating at a certain speed, $u_2$, $u_2'$, and $\beta_2$ of the exit diagram are fixed. The exit diagram for the point of maximum efficiency could be completed if we knew the angle $\alpha_2$ which the absolute velocity makes with $u_2$. The casing, therefore, determines this angle.

From the general theory of the centrifugal pump we know that the flow of water in the casing, after leaving the impeller is governed by the equation:

$$r \times C_u = \text{Constant} \qquad [21]$$

where $r$ is the distance of the particular molecule of water from the axis and $C_u$ the component of its velocity in a tangential direction. Equation [21] is that of a hyperbola which has the axes of ordinates and abscisses as asymptotes. At the exit of the impeller $r = r_2$ the impeller radius, and $C_u = C_{u2}$ as given by the exit diagram, so that

$$rC_u = r_2C_{u2} \qquad [21']$$

If the largest section of the volute is given, Equation [21'] affords a means of calculating at every point of the head $PP'$ (Fig. 19) the corresponding $C_u$ and thus obtaining $AB$ as the curve of velocities. These velocities are theoretical. In reality friction and other reasons reduce these velocities, so that the real velocity curve under which the capacity flows in the case is $AB'$.

Taking now an element $dF$ of the volute area at the radius $r$ and $C_{ut}$ its corresponding theoretical velocity, from the curve $AB$, the corresponding effective velocity $C_{ue}$ is obtained from the curve $AB'$. The real capacity $Q$ flowing through the case is then given by the equation

$$Q = \int_{r_2}^{r_3} dFC_{ue}$$

The same integration with the theoretical velocities

$$\int_{r_2}^{r_3} dFC_{ut}$$

would give a capacity larger than the real capacity.

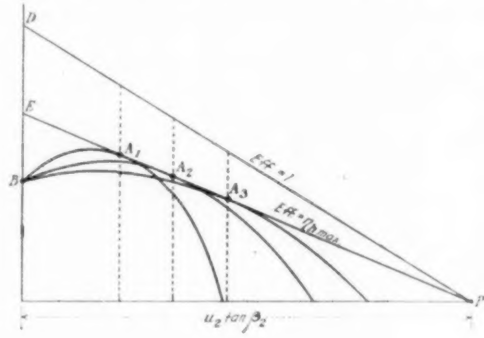

Fig. 17

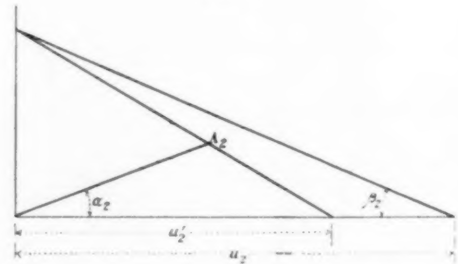

Fig. 18

### The Casing Factor

The ratio of this theoretical capacity to the effective capacity is now taken as a casing factor, or

$$K = \frac{\int_{r_2}^{r_3} dFC_{ut}}{\int_{r_2}^{r_3} dFC_{ue}} \qquad [22]$$

The analysis of the impeller allows us now to deduce from the tests this factor $K$. The capacity at the point of maximum hydraulic efficiency is known and from the exit diagram $C_{u2}$ is obtained, therefore the curve $AB$, determined from the pump dimensions, is the largest volute section. Therefore $\int dFC_{ut}$ can be determined, if not analytically then always graphically and thus the factor $K$ be found. In the example given, the capacity at maximum hydraulic efficiency was 1940 gal. per min. = 4.3 cu. ft. per sec., and $C_{u2}$ was found to be 43.4 ft. per sec. The graphical integration of $\int dFC_{ut}$ gave 6.25 cu. ft. per sec.

Therefore

$$K = \frac{6.25}{4.3} = 1.45$$

When calculating the largest volute section for a new pump we calculate with the theoretical curve $AB$ and with a capacity

K times larger than the real one. Having found this largest section we introduce the effective-velocity curve $AB'$ so that the integration over the known largest volute section gives the effective capacity. We are thus able to determine all the other sections around the volute.

Returning to the problem of connecting impeller and casing, we have to introduce the one element common to both, and this is the flow through impeller and casing at the point of maximum

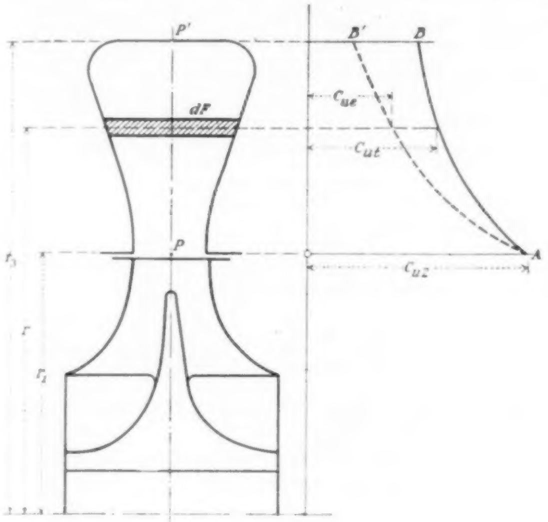

Fig. 19

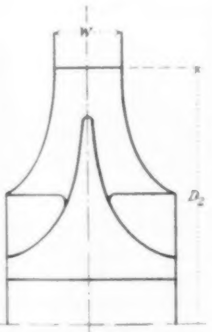

Fig. 20

efficiency. Leakage makes the flow through the impeller somewhat larger than through the casing.

Calling $Q$ now the flow passing the casing, we then have at the exit of the impeller

$$Q + Q_{\text{leak.}} = \phi\pi D_2 W C_{r2}$$

$\phi$ is the ratio between the free exit section and $\pi D_2 W$, $D_2$, and $W$ as shown in Fig. 20. If we put

$$\frac{Q + Q_{\text{leak.}}}{Q} = \epsilon$$

where $\epsilon$ = coefficient of leakage, then

$$Q = \frac{\phi \cdot \pi \cdot D_2 \cdot W \cdot C_{r2}}{\epsilon} \qquad [23]$$

The capacity through the case is given by

$$Q = \frac{1}{K}\int_{r_2}^{r_3} dFC_{ut}$$

From Equation [21′] we deduce that

$$C_{ut} = \frac{r_2}{r} \cdot C_{u2} = \frac{D_2}{2r} C_{u2}$$

and therefore

$$Q = \frac{1}{K}\int_{r_2}^{r_3} dF\,\frac{D_2}{2r} \cdot C_{u2} = \frac{D_2C_{u2}}{2K}\int_{r_2}^{r_3}\frac{dF}{r} \qquad [24]$$

Equations [23] and [24] combined give

$$\frac{\phi\pi D_2 \cdot WC_{r2}}{\epsilon} = \frac{D_2C_{u2}}{2K}\int_{r_2}^{r_3}\frac{dF}{r}$$

and

$$\frac{C_{r2}}{C_{u2}} = \tan\alpha_2 = \frac{\epsilon}{2\pi K\phi W}\int_{r_2}^{r_3}\frac{dF}{r} \qquad [25]$$

Equation [25] connects the impeller and casing. $\int\frac{dF}{r}$ is a purely geometrical value characterizing the largest volute section. It can always be found for every shape of volute by a graphical integration. We now have all the elements of our exit diagram for the point of maximum hydraulic efficiency and therefore know $C_{r2}$ representing the capacity, and $C_{u2}$ representing the total head. In Equation [19] we found that

$$C_{u2} = u_2'\left(1 - \frac{C_{r2}}{u_2\tan\beta_2}\right)$$

If $C_{r2} = C_{u2}\tan\alpha_2$,

$$C_{u2} = u_2'\left(1 - \frac{Cu_2 \cdot \tan\alpha_2}{u_2\tan\beta_2}\right)$$

hence

$$C_{u2} = \frac{u_2'}{1 + \dfrac{u_2'\tan\alpha_2}{u_2\tan\beta_2}} \qquad [26]$$

and

$$C_{r2} = \frac{u_2'\tan\alpha_2}{1 + \dfrac{u_2'\tan\alpha_2}{u_2\tan\beta_2}} \qquad [27]$$

We are now able to obtain the equations for the capacity and total head of a given impeller and given casing.

$$Q = \left(\frac{\phi\pi D_2 \cdot W}{\epsilon}\right)\left[\frac{u_2'\tan\alpha_2}{1 + \dfrac{u_2'\tan\alpha_2}{u_2\tan\beta_2}}\right] \qquad [28]$$

$$H = \left(\frac{u_2u_2' - u_1u_1'}{g}\right)\left[1 - \frac{\dfrac{u_2'}{u_2}\cdot\tan\alpha_2}{\dfrac{u_2'}{u_2}\tan\alpha_2 + \tan\beta_2}\right] \qquad [29]$$

where $\tan\alpha_2$ is determined by Equation [25].

Equations [28] and [29] may be used to calculate a new pump as well as to determine the capacity and head of a pump of given dimensions. They will also be useful in all the many cases of practice where for a given impeller a new case is used or, inversely, a new impeller is made for a given case, and where the exit angle of an impeller is changed or its diameter is reduced. In the latter case, so often applied in centrifugal-pump practice, $u_2$ and $u_2'$ vary in the same proportion as the diameters and Equation [28] shows that the capacities vary as the square of the diameters, whereas Equation [29] indicates that the head is even reduced a little more than would correspond to the square of the diameters.

## Conclusions

The discrepancy between the theoretical results of the classical one-dimensional theory used in calculating centrifugal pumps

and the actual practice, forces us to introduce correction factors which can only be deduced from tests. The designer of centrifugal pumps has at his disposition an abundant amount of ordinary performance curves. This paper has shown a graphical as well as an analytical method of determining from these test curves all the correction factors necessary to bring in accordance theory and practice. At the same time these correction factors have been introduced into the equations of the classical one-dimensional theory, and new equations have thus been developed which can be used for calculating new pumps, on the supposition that these correction factors are known.

It should be noted that the analysis presented is based mainly on the brake-horsepower curve, and its accuracy stands or falls with the accuracy of that curve. Only curves obtained by direct measurement of the b.hp. through torsion or electrical dynamometers should be used, and it is advisable to measure very carefully that portion of the curve around the points of maximum efficiency.

## Discussion

A. F. Sherzer.[3] The early part of the paper[4] states: "But we know that the equation of the total head in the one-dimensional theory indicates a far greater head than the pump actually creates. We shall therefore have to change the classical theory and introduce into it those physical factors which are the reason for the lesser action of the real pump."

He then lists the following factors which bring about this difference:

1 Change in angle of water leaving the blades
2 Whirl component at exit
3 Rotation component at entrance
4 Case factor.

It is not denied that any or all of these may have something to do with the action of the pump, but they are not by any means the sole reason for the lack of agreement between the actual head developed and that called for by the equation for the total head presented in the paper. Concerning the above four factors, which are claimed to represent the reason for the observed lack of agreement, I have little to say, except that the difference between the angle of the water and that of the blade is so slight, if any, that it does little to bring about any agreement.

The whirl component at exit referred to does not seem at all rational, except, possibly, at small rates of flow near shut-off. When operating at the point of best efficiency, it probably does not exist. There is little direct evidence to show that it does, and several carefully made tests to prove that it does not.

The rotation component at entrance is, in my opinion, always present and certainly does increase the head as a result of it. It is hard to see how it could possibly decrease the head, as is claimed by the author. The use of the case factor is very hopeful and, to my mind, entirely correct as a matter of principle. The effect of the case has had scant attention in much of our pump literature.

I would take exception to the statement that Equation [1] of the paper correctly represents the total head developed by a centrifugal pump. This equation

$$H = \frac{1}{g}(u_2C_{u2} - u_1C_{u1})$$

[3] Associate Professor, Department of Mechanical Engineering, University of Michigan, Ann Arbor, Mich.

[4] This discussion is intended by the writer to apply also to the paper, "A New Method of Separating the Losses in a Centrifugal Pump," by M. D. Aisenstein. See paper No. HYD-50-1.

is often claimed to represent either the action of the water turbine or that of the centrifugal pump, provided proper change in notation is used. As it stands, it is no doubt correct for the turbine, but does not hold for the pump. The reason for this is easily seen to be the fact that, in the turbine, the item $u_1C_{u1}$ represents the effect of the angular momentum retained in the water at discharge from the turbine runner, and which may, in cases, oppose the rotation, while in the centrifugal pump all the angular momentum possessed by the water at discharge from the runner has been obtained from it. For this reason, the term $u_1C_{u1}$ does not apply. This is the real reason for dropping the last term, and not, as the author suggests, by reason of the radial entrance of the water which is probably never realized in an actual pump.

With the above change, the equation now becomes:

$$H = \frac{1}{g}u_2C_{u2}$$

and by application of trigonometry, it may be written in the form given by the author in Equation [1] as

$$H = \frac{u_2^2}{g}\left(1 - \frac{C_{r2}}{u_2 \tan \beta_2}\right)$$

The writer prefers a slight modification of the above equation, and would proceed as follows:

$C_{u2} = C_2 \cos \alpha_2$ and $C_2 \cos \alpha_2 = u_2 - w_2 \cos (180° - \beta_2)$ or $C_{u2} = u_2 + w_2 \cos \beta_2$. See Fig. 21.

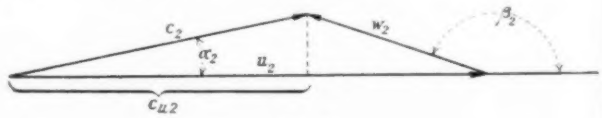

Fig. 21

Now if this value of $C_{u2}$ be substituted in the original equation:

$$H = \frac{1}{g}u_2C_{u2} = \frac{u_2^2}{g} + \frac{u_2w_2}{g}\cos \beta_2 = H \ldots\ldots [30]$$

This is the equivalent of the author's Equation [1'], but is in a form that better illustrates the point the writer desires to make.

The exact physical meaning of the Equation [30] seems to have been completely lost sight of in our present pump literature, and the conditions under which it may be applied are not generally known. That the conditions under which it may be applied are not those found in the centrifugal pump has also been lost sight of, but can be easily proved.

The conditions under which the author's Equation [1'], or the writer's Equation [30], hold are as follows:

1 That each particle of water is introduced at the center
2 That the water is free to accelerate radially in accordance with the motion given to it by the impeller
3 That there are no losses due to the flow through the impeller.

The second of these is the most important. This requires that the water be discharged from the impeller into the atmosphere, and that there be no case to restrain the water from taking on any velocity it may be given by the runner. That is, the present theory is a purely kinetic one and assumes that the total head is represented by the absolute velocity of discharge from the impeller. This is, of course, never realized in an actual centrifugal pump, and hence the theory does not at all agree with the real facts. At first thought, there are probably few who would agree with the above statement. It will therefore be of interest to submit the following proof.

Assume a centrifugal pump, Fig. 22, of a very simple form made by inserting two pipes into a small central pipe supplied with water from a tank. The pipes may be either straight or curved, and we may consider the action of various degrees of curvature. Suppose in the first case the arms be radial.

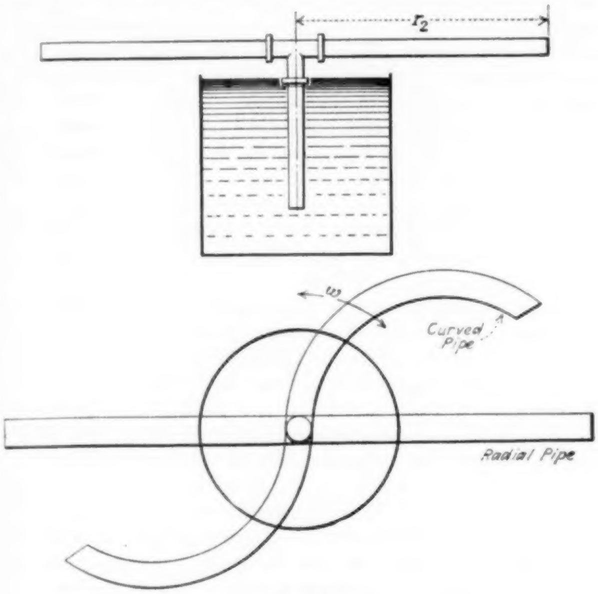

Fig. 22

It can be shown[5] that if the water were introduced at the center at atmospheric pressure and the pressure at the exit of the tube were also atmospheric, friction being neglected, the water will discharge with a relative velocity $w_2$ equal to the peripheral speed $u_2$. This is true not only for radial vanes, but for either forward- or backward-curved vanes as well, under the above conditions. In such cases, it is evident that the total energy given to the water is represented by the absolute velocity of discharge $C_2$ and equal to $\dfrac{C_2^2}{2g}$ per each pound of water. We may have three cases as shown in Fig. 23.

In the first case the water would discharge with a relative velocity $w_2 = u_2$ and in the opposite direction; hence the two would cancel, and the energy given to the water would be zero. In the second case the relative velocity $w_2 = u_2$ is radial and the absolute velocity makes an angle of 45 deg. with the tangent and $C_2 = \sqrt{2}\, u_2$. The kinetic energy per pound of water is therefore $\dfrac{C_2^2}{2g} = \dfrac{u_2^2}{g}$. In the third case the relative velocity $w_2 = u_2$ is directed forward in the same direction as $u_2$, whence $C_2 = 2u_2$ and the total head is:

$$\frac{C_2^2}{2g} = \frac{2u_2^2}{g}$$

Apparently, then, the energy given to the water may vary from zero to $2u_2^2/g$ according to the curvature of the vanes.

Now considering the application of this to Equation [30],

$$H = \frac{u_2^2}{g} + \frac{u_2 w_2}{g} \cos \beta_2$$

when $\beta_2 = 0$, $\therefore \cos \beta_2 = +1$; and since $u_2 = w_2$

$$H = \frac{u_2^2}{g} + \frac{u_2^2}{g} = \frac{2u_2^2}{g}$$

This is exactly the value called for by the kinetic theory given above. Or, when $\beta_2 = 180$ deg., $\cos \beta_2 = -1$, and since $u_2 = w_2$,

$$H = \frac{u_2^2}{g} - \frac{u_2^2}{g} = 0$$

This again shows the agreement of the kinetic theory with the author's Equation [1′]. As was shown before, the author's Equation [1′] could be written as

$$H = \frac{u_2^2}{g} + \frac{u_2 w_2}{g} \cos \beta_2,$$

where $w_2$ is the relative velocity at discharge from the impeller. Now from the discharge diagram, Fig. 24, and since under the conditions of free radial acceleration $w_2$ is equal to $u_2$ in magnitude, and the entire energy given to the water is represented by the kinetic energy of the absolute velocity $C_2$, it is clear that

$$H = \frac{C_2^2}{2g}$$

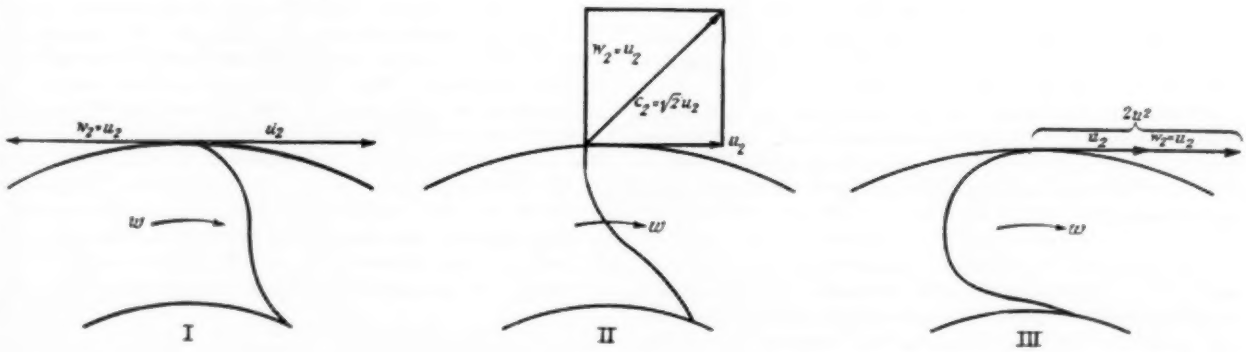

Fig. 23

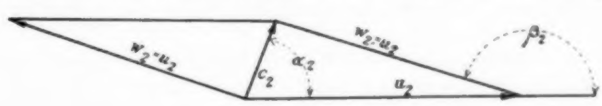

Fig. 24

Now $C_2^2 = u_2^2 + w_2^2 - 2u_2 w_2 \cos (180 - \beta_2)$, or

$C_2^2 = u_2^2 + w_2^2 + 2u_2 w_2 \cos \beta_2$. Now since $u_2 = w_2$

$C_2^2 = 2u_2^2 + 2u_2 w_2 \cos \beta_2$, and dividing by $2g$,

$$\frac{C_2^2}{2g} = \frac{2u_2^2}{2g} + \frac{2u_2 w_2}{2g} \cos \beta_2, \text{ or}$$

[5] See paper by the writer, "A New Theory and Analysis of the Centrifugal Pump," Proc. A.S.C.E., Oct., 1927.

$$\frac{C_2^2}{2g} = \frac{u_2^2}{g} + \frac{u_2 w_2}{g} \cos \beta_2$$

which is identical with the writer's Equation [30] and can be easily changed to the author's Equation [1].

This should make it clear that the $H$ in the author's Equation [1'] is nothing more or less than the kinetic energy $\frac{C_2^2}{2g}$ and holds only for such a kinetic pump. It goes without saying that free radial acceleration is never realized in any actual centrifugal pump, nor is it even closely approached; hence the observed difference. The theory proposed by the author is more nearly that of a mechanical lawn sprinkler than of a modern centrifugal pump.

W. M. White.[6] The author has made a real effort to find a solution that would be of benefit to the designer. The only criticism of the method is that it is too complicated. There is no time in the manufacturing plant to analyze the various pumps constructed and tested even in accordance with the analytical method.

The writer cannot agree with the author that the flow occurs as the arrow indicates in Fig. 1. There may be a tendency to flow in that direction, and there is a difference in velocity across the channel formed by the two vanes of the impeller, but that there is an actual reversal of flow is open to doubt.

The form of casing illustrated in Fig. 19 is interesting, but the author's statement that "the discrepancy between the theoretical results of the classical one-dimensional theory used in calculating centrifugal pumps and the actual practice forces us to introduce correctional factors that can only be deduced from tests," leads one to doubt that that is the final proper design of a spiral casing. We must still do what we have done for 25 years: depend on tests and formulas to direct us in design.

Nevertheless, the author deserves credit for the painstaking work he has done. The paper will undoubtedly lead to considerable study in the direction indicated, with an ultimate result of securing a method of design that can be used in the rush of modern business.

A. L. McHugh.[7] The writer cannot agree with the statement of Mr. White that the method outlined by the author is too laborious to be useful. A paper such as this one on centrifugal pumps, setting forth theories and methods of analysis, is a step in the right direction. It will lead to studies that will be helpful to industry. There have been too few papers of this character before the Society.

The writer has made a few analyses of impellers made by his company, according to the author's method. On the whole the theory seems sound, and good results can be obtained with it.

M. G. Robinson.[8] The writer's work deals with air compressors and not with centrifugal pumps, although fundamentally the air compressor is the same machine as the centrifugal pump. It is well known that due to a finite number of blades in an actual impeller, the pressure developed by a centrifugal air compressor is not as high as the usual classical theory would indicate. There is every reason to believe that the average angle which the relative velocity of the fluid makes with the peripheral velocity of the wheel, is less than the angle of the blade as constructed.

[6] Chief Engineer, Allis-Chalmers Mfg. Co., Milwaukee, Wis. Mem. A.S.M.E.

[7] Chief Engineer, Goulds Pumps (Inc.), Seneca Falls, N. Y. Mem. A.S.M.E.

[8] Research Engineer, General Electric Co., Lynn, Mass. Assoc-Mem. A.S.M.E.

In the author's example, a 20-deg.-blade centrifugal pump performs as if it had an angle of 14 deg. 45 min. This is a reduction of 25 per cent with a correspondingly large reduction in the pressure-generating capacity of a wheel of a given diameter running at a given speed. In centrifugal compressors, due to the relatively low density, and consequently higher speed required, angles as low as 20 deg. are practically unknown, the usual range being 90 deg. to 45 deg. Experience points to the fact that with such steep angles the decrease in the actual blade angle is not apt to be so pronounced.

In connection with a series of tests made at Lynn on air compressors with casings of two types, the following conclusion was arrived at: That the use of a casing with a volute with guide vanes causes less of a decrease in the blade angle than there would be when using a casing without guide vanes. The writer would like to inquire if the author has had any similar experience with a centrifugal pump.

The reason why the actual effective angle of a blade should be determined is to enable the manufacturer to show the entire characteristic curve of the machine; It is fairly easy to get a guaranteed performance for one point only, but in order to draw the entire curve from no load to zero pressure, it is absolutely necessary to know what the actual effective blade angle is, not judging entirely from the construction of the blade.

Sanford A. Moss.[9] A fundamental criticism could be applied to all methods of analysis similar to those set forth by the author. The centrifugal pump has one point of maximum efficiency, where vane angles and passage areas are correct and at which all losses are reduced to a minimum. At that point it is desirable to know the losses. If they can be determined and reduced the pump can be improved. At other points the losses are increased, due to incorrect angles and areas, and sometimes due to absurd conditions. When an attempt is made to analyze the performance by using the entire performance curve, a handicap is encountered which prevents one from obtaining the losses at the point of best efficiency by reason of the absurd conditions at the extreme points.

The Author. The equation of the total head

$$H = \frac{1}{g}(u_2 C_{u2} - u_1 C_{u1}) \quad \ldots\ldots\ldots\ldots\ldots [1]$$

is nothing else but a special expression of the law of conservations of energy. It simply states that if a fluid containing the energy $E_1$ enters a system (in our case the impeller) and leaves this system with the energy $E_2$, the difference $E_2 - E_1$ must have been given to the fluid by this system (losses excluded) regardless of the nature of process within the system. This equation is therefore of a very general and fundamental character and expresses the energy given to the water by the impeller independently of the particular design of the impeller, or the particular conditions under which the impeller is working. Equation [1] gives the total head of a kinetic-pump runner as well as of an impeller surrounded by a pressure chamber (centrifugal pump). It expresses the total head of a radial pump, where a centrifugal force is acting, as well as of a purely axial pump.

It is therefore not surprising at all that when Professor Sherzer applies this equation to the special case of the kinetic pump where no difference of pressure is generated between the entrance and exit of the impeller, he finds that it reduces to the value $\frac{C_2^2}{2g}$, the total head of a pump under these particular conditions.

[9] Engineer, Thomson Research Laboratory, General Electric Co., Lynn, Mass. Mem. A.S.M.E.

But the author fails to understand how Professor Sherzer concludes from this evident fact that Equation [1] is therefore *only* to be applied to a kinetic pump and not applicable to a pump working under other conditions. To clear the situation, he will indicate roughly how Equation [1] can be derived, proceeding from the law of energy and with assumptions entirely different from those of the kinetic pump. In other words, assume that the pressure at the exit of the impeller is greater than at the entrance, and that the relative velocity $w_2$ at exit is not equal to the peripheral velocity $u_2$.

In the following, in speaking of the energy of the liquid we shall always have in mind the energy of the unit of weight of this liquid.

Let $\gamma$ be the specific gravity of the liquid (see Fig. 25), and $C_1$ and $P_1$ the velocity and pressure of the liquid at entrance (the pressure measured from atmospheric). The liquid before entering the impeller then possesses the energy

$$E_1 = \frac{C_1^2}{2g} + \frac{P_1}{\gamma}$$

If $C_2$ and $P_2$ are the velocity and pressure of the liquid after leaving the impeller, its corresponding energy is

$$E_2 = \frac{C_2^2}{2g} + \frac{P_2}{\gamma}$$

The law of energy states that the increase $E_2 - E_1$ in energy can only have come through the action of the impeller. The impeller has therefore created the total head

$$H = \frac{C_2^2 - C_1^2}{2g} + \frac{P_2 - P_1}{\gamma} \quad \text{. . . . . [a]}$$

Now in a centrifugal pump we have two sources of creating pressure within the channel of the blades. The first is through diffusion, changing velocity into pressure—in our case, reducing the relative velocity $w_1$ at entrance to the relative velocity $w_2$ at exit, with a corresponding gain in pressure of $\frac{w_1^2 - w_2^2}{2g}$. The second is through centrifugal force, the corresponding creation of pressure in this case being $\frac{u_2^2 - u_1^2}{2g}$.

Therefore

$$\frac{P_2 - P_1}{\gamma} = \frac{w_1^2 - w_2^2}{2g} + \frac{u_2^2 - u_1^2}{2g} \quad \text{. . . . . . . . . . . [b]}$$

The total head is now

$$H = \frac{C_2^2 - C_1^2}{2g} + \frac{w_1^2 - w_2^2}{2g} + \frac{u_2^2 - u_1^2}{2g} \quad \text{. . . . . . . [c]}$$

The energy contained in the liquid at entrance may come from an outside source, or may have been given to the water by the action of the atmospheric pressure. In the latter case $(P_1/\gamma)$ is negative and Equation [a] shows that the impeller has to create the corresponding energy. From the entrance and exit velocity diagrams of Fig. 25 we conclude that

$$w_1^2 = u_1^2 + C_1^2 - 2u_1 C_1 \cos \alpha_1$$

$$w_2^2 = u_2^2 + C_2^2 - 2u_2 C_2 \cos \alpha_2$$

Substituting these values in Equation [c],

$$H = \frac{1}{g}(u_2 C_{u2} - u_1 C_{u1}) \quad \text{. . . . . . . . . . . . . . [1]}$$

which is the basic equation of the total head of this paper. The foregoing shows that Equation [1] is a general equation embracing all cases of pumping conditions and including as a special case the kinetic pump referred to by Professor Sherzer. For the kinetic pump $P_1 = P_2$ and Equation [b] then gives $\frac{u_2^2 - u_1^2}{2g} = \frac{w_2^2 - w_1^2}{2g}$. In case the water enters centrally as Professor Sherzer assumes, $u_1 = 0$ and $w_1 = 0$, and therefore $u_2 = w_2$. And Equation [a] for $P_1 = P_2$ and $C_1 = 0$ shows that for this case $H = C_2^2/2g$.

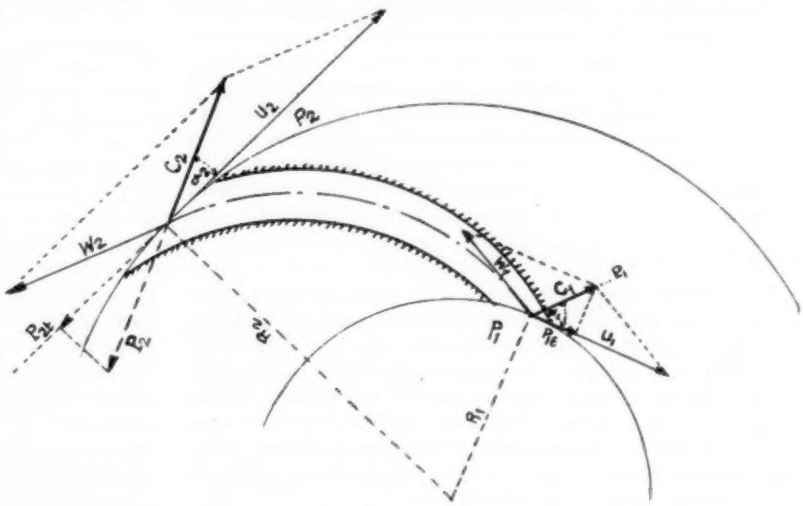

Fig. 25

In order to make the value $u_1 C_{u1} = 0$, Professor Sherzer has to assume that the water must enter the impeller at the center. But this assumption is not necessary at all and the author did not have to make use of it in developing his equation. The water may enter the impeller at any distance from the center. If it arrives with a velocity $C_1$ at an angle $\alpha_1$ with the peripheral velocity, Equation [1] indicates the corresponding created head. If the velocity $C_1$ is normal to the peripheral velocity the head is $H = 1/g\ u_2 C_{u2}$, even if the water enters the impeller at a distance from the center.

In his discussion Professor Sherzer states that it is hard to see how the entrance rotation could decrease the head. In his opinion it could only increase it. And later he says: "In the centrifugal pump all the angular momentum possessed by the water at discharge from the runner has been obtained from it. For this reason the term $u_1 C_{u1}$ does not apply." To clear away this objection let us consider the equation of the angular momentum obtained by dividing the equation of the total head by the angular velocity. (See Fig. 25.)

$$M = \frac{1}{g}(r_2 C_{u2} - r_1 C_{u1}) \quad \text{. . . . . . . . . . . . . . . [d]}$$

The impulse force per unit of weight at the exit is equal to $\frac{1}{g} C_2$ and acts in the direction of $C_2$. The corresponding reaction force on the impeller is equal to this impulse force but in an opposite direction. The tangential component of the reaction force is therefore equal to $\frac{1}{g} C_{u2}$ and is opposite to the rotation. This

force acts as a resistance to the rotation of the impeller, and the impeller in overcoming it has to do the work $\frac{1}{g} C_{u2} \cdot u_2$. At the entrance, however, the impulse force of the water is $\frac{1}{g} C_1$ in the direction of $C_1$, and the reaction on the impeller is in the same direction. The tangential component of this force is $\frac{1}{g} C_{u1}$ in the direction of the rotation. This force therefore supports the impeller in its action and does the work $\frac{1}{g} C_{u1}u_1$. The work which the impeller alone has done is therefore the difference $\frac{1}{g} (u_2C_{u2} - u_1C_{u1})$.

Stated in another way, the impeller assisted by the atmospheric pressure gives to the water the velocity $C_1$ before it enters the impeller. If this water enters the impeller so that $C_1$ has a tangential component, then it is able to return to the impeller a part of the energy it received. Therefore the energy which the water has received from the impeller is diminished by this amount. In case, however, that the water enters the impeller so that $C_1$ is normal to the tangential direction, then it is not able to return to the impeller any energy, and the total energy received by the water from the impeller is then $\frac{1}{g} u_2C_{u2}$.

The equation of the total head is based on certain assumptions which do not conform well with the actual pump as shown in the paper. For this reason the equation had to be transformed and those physical factors introduced which the equation neglected. As far as the author knows, all the physical factors influencing this equation have been considered in the paper. He thinks that the development of Equation [1] clearly shows that Professor Sherzer's idea that this equation is only applicable to the kinetic pump is not sound.

In regard to the criticism made by Professor Sherzer as well as by Mr. White concerning the whirl flow, there seems to be quite considerable misunderstanding on this subject. The whirl flow is nothing else but the hydrodynamic explanation of how a runner with only a small number of blades is able to transmit the necessary forces to the water. Fig. 1 of the paper does not represent the actual flow of the water through the channels of the blades, but only a component of this flow. In other words, the flow through the channel is composed of the main flow and this whirl flow. At normal rates of flow the velocity due to the main flow is much higher than the backward velocity of the whirl on the acting side of the blade. Therefore a reversal of flow does not occur. But at small rates of flow this whirl velocity may be higher and then a reversal takes place. The whirl flow is not some kind of an eddy current connected with energy losses. It exists whenever energy is transmitted from the blades to the water and it exists because of this fact. The result is that a runner with only a small number of blades is not able to create as high a pressure as one with an infinite number of blades would be able to do under the same conditions. The whirl flow disappears only when there is no transmittance of energy to the water; that is in the case of a purely radial flow through the impeller. There is a case where the whirl flow theoretically does not exist and this is in the purely axial pump. Here exertion of forces by the blades on the water is only possible because of change of directions of the flowing water—a reason why the axial pump is so much more unstable in its creation of pressure than the centrifugal pump.

Mr. White's remarks about the proper design of the spiral casing are not quite clear to author. The paper shows that for a pump of given conditions of capacity and head the volute section is determined; but without any preference being given to a particular shape of casing. The only condition imposed is that in calculating the volute only the actual section passed by the water shall be considered. Tests will always be necessary to the development of the centrifugal pump, and one of the main tasks of the paper is to indicate methods of extracting from those tests all the knowledge which is not readily apparent.

Mr. Robinson's experiences concerning the difference of blade angle and fluid angle in air compressors with and without guide vanes are very interesting. The author has not had a chance as yet to analyze many guide-vane pumps. But the fact that in a guide-vane compressor the angle difference is smaller is not surprising. The difference between blade angle and fluid angle may be traced to two sources. The first is the difference which takes place within the channel of the blades and forces the fluid to leave the blade walls. The second is the reaction of the flow in the casing on the flow in the impeller. In the case of the guide-vane compressor this reaction is probably prevented and the angle difference therefore reduced.

Replying to Dr. Moss, the author would say that the method described in the paper does not employ the entire performance curve for the purpose of analysis, but only a very narrow range around the points of maximum efficiencies. In a centrifugal pump there does not exist just one point where all losses at the same time are minimum. The point of best hydraulic efficiency is different from the point of maximum total efficiency. And the point of maximum total efficiency does not necessarily correspond with the point where the shock losses are a minimum. So the use of the range of the curve where all these optimum points are located seems therefore to be quite justified.

# Centrifugal Pumps

## General Considerations Regarding Losses, Disk Friction, Specific Speed, Etc.—Principles Governing Design of Volute, Suction and Delivery Pipes, Impeller, Bearings and Glands, Priming Apparatus, Etc.—Materials of Construction

By H. T. DAVEY,[1] BEXLEY HEATH, KENT, ENGLAND

ALTHOUGH originally regarded as a means of raising large quantities of water against low heads with a fair degree of efficiency, centrifugal pumps of modern design are used for a variety of purposes, and in many cases, using high speeds of rotation, high lifts have been obtained. This is particularly so with the turbine pumps, in which the highest efficiencies are obtainable.

It is obvious that a pump can only be designed to give efficient results under one set of working conditions, and therefore it must always be run at the designed speed if best results are to be obtained. Centrifugal pumps are therefore best suited to work of constant character.

Of the many uses to which these pumps are put, the following may be regarded as the most important:

(*a*) Irrigation
(*b*) Drainage
(*c*) Circulation
(*d*) Suction dredging.

For irrigation purposes the greater market is in countries where the rainfall is uncertain or comes at one particular season of the year. In low-lying country, where rain is abundant, centrifugal pumps are used for drainage, as in Holland, where some of very large size are in use. Many pumps used for these purposes have delivery pipes five and six feet in diameter and are therefore capable of dealing with large quantities of water. For dredgers, special material must be used for the pumps on account of the solid matter which is drawn through them with the water.

The efficiency of a centrifugal pump is dependent upon the extent to which the kinetic energy of the fluid at discharge from the disk can be changed into pressure energy in the volute or casing. The velocity of the fluid leaving the disk will be high, and therefore, in order to prevent losses, or at least minimize them, the volute must be designed to gradually reduce this high velocity of discharge to that of the fluid in the pipes; unless this change is gradual, energy will be lost by the setting up of eddies in the volute, which will lower the efficiency. The usual form of pump casing is spiral, the cross-sectional area increasing toward the delivery branch, the area being proportional at any section to the quantity of fluid flowing through it.

To secure the best results and highest efficiency, the fluid must be taken into the suction pipe at a low velocity and delivered also at a low velocity, the maximum speed being obtained in the pump.

Centrifugal pumps are made with single and double inlets. The latter type seems preferable since end thrust on the shaft is eliminated, and therefore no special precautions are necessary, the disk being balanced by the incoming water. In actual practice, however, the single-inlet type is often manufactured, particularly for very light duties; the cost of manufacture of this type of pump is somewhat less than that of the double-inlet type.

For lifts over 100 ft., multi-stage pumps are manufactured, having two or more impellers, according to the duty which the pump is called upon to perform; but for lifts up to 100 ft. the single-impeller pump is efficient.

### Calculations

Throughout this paper the following symbols will be used:

$\omega$ = angular velocity of disk, in radians per second
$r_1$ = radius of periphery of eye, in feet
$r_2$ = radius of periphery of disk, in feet
$u_1$ = linear velocity of periphery of eye, in feet per second
$u_2$ = linear velocity of periphery of disk, in feet per second
$u_a$ = absolute velocity of discharge from disk, in feet per second
$\alpha$ = angle of vane tip at entry
$\gamma$ = angle of vane tip at exit
$v$ = velocity of discharge in feet per second
$V_r$ = radial velocity of flow at entry, in feet per second
$V_R$ = radial velocity of flow at exit, in feet per second
$V_V$ = velocity of flow in volute, in feet per second
$V_W$ = velocity of whirl at periphery of disk, in feet per second
$v_d$ = velocity of flow in delivery pipes, in feet per second
$v_s$ = velocity of flow in suction pipes, in feet per second
$Q$ = quantity of water flowing, in cubic feet per second (total)
$W$ = weight of 1 cubic foot of water = 62.4 lb.
$g$ = acceleration due to gravity = 32.2 ft. per sec. per sec. [approx. in London, 32.18]
$H$ = total height in feet to which water is raised by pump = head
$H_m$ = total head against which pump is working, in feet, or the manometric head
$H_P$ = head of water lost in pipe friction, in feet
$L_h$ = hydraulic losses
$L_m$ = mechanical losses.

Fig. 1 shows a typical velocity diagram for a centrifugal pump of the usual construction, and employs a number of the above symbols.

Of the three efficiencies usually considered in connection with centrifugal pumps, the working efficiency, or what may be called the overall efficiency, is the most important, from several points of view. This efficiency is the ratio of the work done by the pump to the work put into it.

$$\text{Working efficiency } \eta_W = \frac{H_m}{\dfrac{V_W u_2}{2g} + L_h + L_m}$$

$H_m$ is equal to $H + H_P + v^2/2g$ and is termed the manometric head. Also,

$$\left.\begin{array}{l}\text{Turning moment on shaft}\\ \text{equivalent to change in}\\ \text{angular momentum per sec.}\end{array}\right\} = \frac{WQ}{g}(V_W r_2 - V_W r_1) \text{ lb-ft.}$$

$$\text{Work done per second} = \frac{WQ}{g}(V_W r_2 - v_w r_1)\omega \text{ ft-lb.}$$

[1] Associate-Member, Institution of Mechanical Engineers.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of The American Society of Mechanical Engineers.

As it is not usual to provide guide vanes in the eye, the velocity of whirl $v_w$ will be zero; this assumes that the water is not made to rotate by friction. Thus assuming radial flow, and since $\omega = u_2/r_2$,

$$\text{Work done per second} = \frac{WQ}{g} V_W u_2 \text{ ft-lb.}$$

and

$$\text{Work done per lb. of water} = \frac{V_W u_2}{g} \text{ ft-lb.}$$

The ratio of $H_m$ to the work done on the water per pound gives the manometric efficiency $\eta_m$.

$$\eta_m = \frac{H_m g}{V_W u_2}$$

From the velocity diagram, Fig. 1, $V_W = u_2 - V_R \cot \gamma$

$$\therefore \eta_m = \frac{H_m g}{u_2(u_2 - V_R \cot \gamma)}$$

The expression thus obtained does not include any losses,

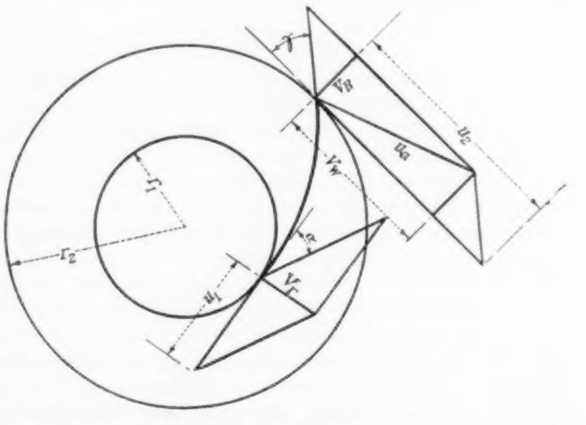

Fig. 1 Typical Velocity Diagram for a Centrifugal Pump of the Usual Construction

and if therefore the hydraulic losses are added, the hydraulic efficiency $\eta_h$ can be obtained:

$$\eta_h = \frac{H_m}{\dfrac{V_W u_2}{g} + L_h}$$

## Losses

The losses in a centrifugal-pumping installation are of two kinds, namely, hydraulic and mechanical. Those losses which arise due to the presence of the fluid may be called hydraulic losses, while losses such as friction at bearings may be called mechanical losses.

In a centrifugal pump and also in the pipe lines connected with it, certain losses will occur, some of which must be taken into account when designing the plant, since they often reach considerable proportions. Every effort must of course be made to keep such losses a minimum.

In the pipe lines there will be friction losses, which can be closely estimated by means of the Darcy formula:

$$H_P = Z\left(1 + \frac{1}{12d}\right)\frac{v^2}{2g} \cdot \frac{4l}{d}$$

In this case $l$ = length of pipes in feet
$d$ = diameter of pipes in feet
$Z$ = constant depending upon the condition of the pipes. For old pipes $Z = 0.01$; for new ones, $Z = 0.005$, the material being cast iron
$v$ = velocity of flow in pipes in feet per second.

Sudden enlargements of pipes, or contractions, will produce hydraulic losses, and should therefore be avoided. Right-angled bends should also, where possible, be avoided.

Hydraulic losses will also occur at discharge. If $v_d$ is the velocity at discharge, the energy lost per pound of water = $v_d^2/2g$ ft-lb.

Again, losses will occur when the water leaving the disk meets the water flowing in the volute. The loss from this cause will be:

$$\frac{(u_a - V_V)^2}{2g} \text{ ft-lb. per lb.}$$

## Disk Friction

The friction of the disk rotating in the fluid also contributes to a large extent toward the losses.

One of the chief influencing factors in regard to the disk friction is the clearance between the faces of the disk and the casing. It has been shown by experiment[3] that, as the clearance increases, so the friction increases, and therefore the

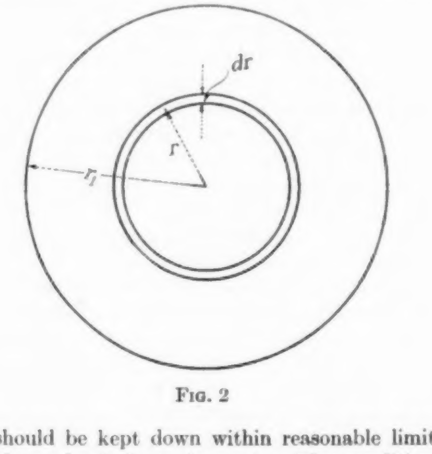

Fig. 2

clearance should be kept down within reasonable limits, compatible with mechanical requirements. The condition of the surface of the casing and disk also has some effect upon the friction, but it is very doubtful if the extra cost of producing highly finished machined surfaces pays, since ordinary painted and varnished faces seem to be just as satisfactory, and more so from some points of view. The viscosity of the fluid will also affect the friction, as will also the velocity of the disk.

Consider a thin strip of the disk with a width $dr$ (Fig. 2), and situated at radius $r$ from the center. Also let

$\rho$ = resistance per square foot of surface per unit velocity
$V_f$ = velocity of fluid relative to disk, in feet per second
$r_1$ = radius of disk in feet
$u$ = velocity of strip $dr$ of disk relative to velocity of fluid, in feet per second.

It has been established by experiment that the friction varies as $u^n$, where $n$ depends upon the clearance of the disk, etc. It is, however, sufficiently accurate for most practical purposes to take $n = 2$, and therefore the friction varies as $u^2$. Also

[3] Proc. Inst. C. E., vol. 80 (1885).

the velocity of the strip will be proportional to its radius $r$, therefore $u = V_f r/r_1$.

Total resistance of wetted surface $= \rho\, 2\pi\, r dr u^2$

$= \rho\, 2\pi\, r^3 dr V_f^2/r_1^2$

Moment of this force $= \rho\, 2\pi\, r^4 dr V_f^2/r_1^2$

Moment of total frictional force on disk $= \rho\, 2\pi\, V_f^2/r_1^2 \int_{r=0}^{r=r_1} r^4 dr$

$= {}^2/_5 \pi\rho V_f^2 r_1^3$

Turning moment due to friction on both sides of disk $= {}^4/_5 \pi\rho V_f^2 r_1^3$

Work lost in friction $= {}^4/_5 \pi\rho V_f^2 r^3 \omega$ ft-lb. per sec.

$= {}^4/_5 \pi\rho V_f^3 r_1^2$ ft-lb. per sec.

The values of $\rho$, as previously mentioned, will depend on the side clearance and the condition of the surfaces of both the disk and the casing. There is, however, a very considerable difference in values for different surfaces and different clearances, the range being from about 0.0132 lb. down to 0.0031, the higher values for the rough surfaces.

The effect of putting vanes on to the disk is to increase the friction. There will also be slight frictional loss due to the flow through the vanes. This will, however, be comparatively small. The friction of the water flowing round the volute will also account for some loss of power, and can be approximately computed from the length of the volute and its diameter.

The above losses are those of most importance, and must be considered when calculating the hydraulic efficiency. There are of course other losses which may occur, such as slip, etc., all tending to reduce the efficiency.

The mechanical losses will depend upon the type and condition of the bearings, and also the kind and condition of packing used in the stuffing boxes. The fit of the impeller in the casing will also have some effect. The actual magnitude of these losses can be determined by running the pump without load and determining the actual power absorbed.

### Speed at Which Pumping Commences

A centrifugal pump will not begin to pump until the speed of the disk is sufficient to create a pressure difference through the disk greater than the total pressure head against which the pump is to work. In order that the pump shall commence working, the angular speed $\omega$ of the disk must be such that $\omega^2(r_2^2 - r_1^2)/2g$ is greater than the total head $H_m$.

### Specific Speed

With respect to a centrifugal pump, the specific speed is the speed at which an exactly similar one of reduced size would require to run in order to deliver 1 cubic foot per second against a total head of 1 foot and give maximum efficiency.

If $N$ = number of revolutions per minute of an actual pump
$Q$ = discharge in cubic feet per second
$H_m$ = total head against which pump operates, in feet, and
$N_s$ = specific speed in revolutions per minute,

then

$$N_s = \frac{N\sqrt{Q}}{H_m^{5/4}}$$

According to various authorities,[3] the specific speed for maximum efficiency should lie between 80 and 240; hence, accepting these conditions, pumps should be designed so as to have specific speeds within this range.

[3] L. T. Moody, *Mechanical Engineering*, April, 1921, and S. F. Sherzer, *Engineering News-Record*, June, 1921.

## GENERAL PRINCIPLES OF DESIGN

Broadly speaking, there are three types of centrifugal pumps in general use:

*a* Single-inlet
*b* Double-inlet single-stage, and
*c* Multiple-stage.

For low lifts and small capacity, the single-inlet pump is the most used, while the separate units in the multi-stage pumps are usually of this construction. As previously mentioned, the cost of production is less than that of the double-inlet type, and the casing more easily made. For small oil pumps and cooling-water circulating pumps for internal-combustion engines, this type is very common. Owing to the end thrust set up by the incoming water, thrust bearings are necessary with this type.

For greater lifts up to 100 ft. and high capacity the double-inlet single-stage pump is largely used, while for high lifts, from 100 ft. to 2000 ft., for best results the multiple-stage pump is most satisfactory. The end thrust is also eliminated in the double-inlet construction, the rotor being balanced by the incoming water.

### The Volute of Casing

Generally, the pump casing is made in two parts, this construction being necessary in order to get the disk into position, and also for cleaning purposes. The joint line is made in one of the four following ways:

1 On a center line in the plane of the pump
2 On a horizontal center line in a plane through the axis of rotation
3 A side cover is provided, the joint line of which is arranged conveniently on the side of the pump
4 As in 3, but with one cover on each side of the disk.

Each method has its good and bad points, but the question is largely one for the judgment of the designer. It may, however, be stated that a single side cover gives an inexpensive job, and is satisfactory for many purposes.

It is important to at once realize that the efficiency of a centrifugal pump depends largely upon the design of the volute. Its duty is to change into pressure energy the kinetic energy of the fluid given to it by the impeller. With this object in view, three principal types of casings have been manufactured:

*a* Volute with whirlpool chamber
*b* Plain volute or spiral casing, and
*c* Casing with guide vanes.

The first type has now gone out of existence, so far as practical work is concerned, but undoubtedly small pumps, well made, and provided with a vortex or whirlpool chamber, gave good results and worked efficiently.

The second type is very common for low and moderate lifts, and when well designed, works very efficiently.

The third type, applied to turbine pumps, is used for very high speeds and generally for high lifts. These represent the most efficient type of pump. Small rotors are used for this purpose.

It has been established by practical tests that the best results are obtained when the velocity of flow in the volute is between $0.3\sqrt{(2gH_m)}$ and $0.4\sqrt{(2gH_m)}$. Since the whole of the water pumped has to pass through the throat, the area here should be such as to allow full flow at a velocity not exceeding that selected from the above values. The area of any cross-section

is proportional to the quantity flowing through it, and therefore the areas of the volute at points *a*, *b*, *c*, *d*, *e*, *f*, Fig. 3, must be proportional to $^1/_4$, $^3/_8$, $^1/_2$, etc., respectively, of the total quantity of water flowing. When such is the case, the velocity

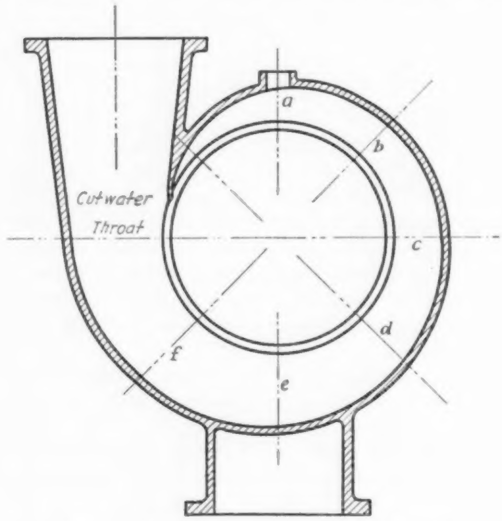

Fig. 3 Diagrammatic View of a Volute

of flow in the volute will be constant. A more or less circular section is maintained throughout. Fig. 4 shows a form of volute cross-section which has been adopted by some makers, but in the opinion of the author, this section, which gradually changes from a very shallow segment to a full circle at the throat, is not desirable since "dead water" tends to collect and lag in the side pockets of the section.

In order to prevent the water flowing through the throat being driven round the casing, a stop or cutwater is necessary. This usually forms part of the main volute casting, and will be clearly seen on reference to Fig. 3; there should be a good clearance between the cutwater and impeller, otherwise vibration during working may occur.

In the case of the turbine pump, the main casting is arranged so that guide vanes can be fitted. These guide vanes are provided so that the area of waterway from the outlet of the disk gradually increases outward, and thus the velocity of discharge falls. In these pumps, the tips of the vanes on the disk are often radial at discharge. The cost of providing these guides is of course considerable, but very high efficiency can be obtained, and if high speeds are used, large quantities of water can be pumped with a comparatively small machine.

## Delivery Pipes

In order to reduce the velocity of flow along the delivery pipes and obtain as much pressure energy as possible from the available kinetic energy, the usual practice is to enlarge the delivery branch of the pump to such an extent that the velocity of flow in the pipes does not exceed 8 or 10 ft. per sec. A common rule is to make the delivery-pipe area twice that of the throat, but there is no general rule in regard to this point. In several pumps with which the author has had experience, the velocity of flow in the pipes has been about half that of the water in the volute. These pumps are giving satisfactory results.

In many cases the delivery pipes have been made abnormally large, in order to reduce the velocity of flow to within 2 or 3 ft. per sec., but the practice is unusual, since large pipes add greatly to the initial cost, and little is to be gained from it. It is also known that, for high lifts, the efficiency falls off when the speed is too low.

When the delivery pipes are short, it is common practice to gradually increase their diameter, so that the velocity at discharge is low, say, about 2 or 3 ft. per sec. In cases where the pipes are long, the delivery branch from the pump is enlarged to give a flow of about 8 or 10 ft. per sec., and a bell mouth is fitted at the delivery end of the pipes. (Fig. 5.)

## Suction Pipes

Wherever possible, the suction pipe should be short. The low efficiency often obtained is due to long suction pipes, air leaks, etc. The best pumps obtainable will not work satisfactorily, if at all, with suction heads greater than 25 or 27 ft.

As with the delivery pipes, the suction is often such that

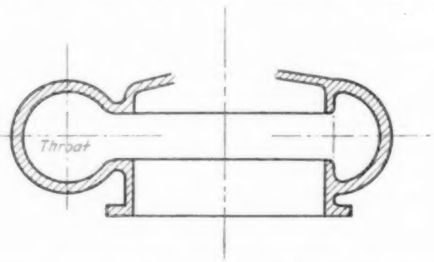

Fig. 4 Cross-Section of a Volute. Segmental Section Changing to Circular at Throat

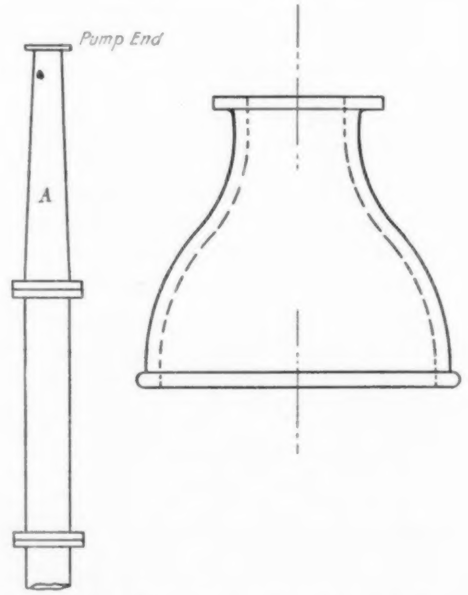

Fig. 5 Reducer for Pump End of Pipe Line and Bell Mouth for Suction and Delivery Pipe Ends

(To reduce friction in long suction pipe lines large-diameter pipes are used. Velocity is increased toward pump by the reducer A in sketch at left.)

the water enters at very low speed, and due to a gradually decreasing pipe diameter, it increases toward the pump. The best results will be obtained if the velocity of the water entering the suction pipe is about 3 ft. per sec., and on reaching the pump is increased to about 6 or 8 ft. per sec.

Many pumps will be found to have suction pipes of the same size as the delivery, but conditions as given above will generally secure the most satisfactory results.

In regard to the suction branches to the eye of the disk, it is good practice to make their combined area slightly in excess

of the suction-pipe area. These should, however, not be excessively large and should lead in as straight as possible, so as to avoid air locks due to pocketing.

### Pipe Diameters, Lengths, Etc.

When fixing pipe diameters it is well to keep in view the standard stock sizes manufactured, since if these have to be specially made, the initial cost is increased.

### The Impeller, Disk, or Rotor—General

Broadly speaking, there are three types of disks in general use:

*a* Single-sided, open or shrouded
*b* Double-sided, open type, and
*c* Double-sided, shrouded type.

The single-sided disk is used largely for single-inlet pumps working against heads up to 100 ft., and also for the large multi-stage pumps fitted with guide vanes in volute. Disks of this type are not generally directly balanced by the water, as is the case with the double-inlet disk, but require special means for balance, such as ball thrust races, or collars, although in some cases they are balanced hydraulically.

The double-sided disk is employed in double-inlet pumps, and is balanced directly by the water flowing into the eye. These disks may be either open or shrouded. If the former is employed, then the disk must form a neat running fit within the casing. If the latter is used, then a fairly large clearance can be made. With regard to this point, it should be borne in mind that the disk friction will increase as the clearance increases, and hence the clearance should be a minimum compatible with mechanical requirements. As far as efficiency goes, there is a tendency for excessive slip to occur with the unshrouded disk, which affects the efficiency adversely.

From the point of view of manufacture, the open type is undoubtedly the easiest and cheapest, since it is much easier to mold, and when cast the channels are so much easier to clean. It is perhaps not quite so easy to produce a good, clean job from the lathe, on account of the intermittent cutting, as may be obtained with the shrouded type; in this case perfectly smooth faces can be produced. It is, however, difficult to clean out the channels in the shrouded disk. These channels are cored out, and in consequence are always somewhat rough.

It is important to notice that, in the case of direct-coupled pumps, the shrouded disk is particularly useful, since end play on the engine or motor shaft does not cause the disk to grind on the casing, as would be the case with the open type. This point is particularly important when electric motors are employed for driving directly, since the armatures are often allowed to float $^1/_4$ in. or so. It is due to the increasing use of electric motors for driving that the shrouded disk is perhaps more commonly used nowadays. The extra weight of metal in the shrouded disk is important from the point of view of cost. In consideration of this, it is to be observed that some pump makers allow large clearances between the shrouded disk and the volute casing, and include this area as part of the cross-sectional area of the volute, thereby saving metal in the volute casting. Hence the extra cost of metal in the disk may be made up by the smaller volute casting, which, in large pumps, may be very considerable. In the opinion of the author, this practice, besides increasing the disk friction, reduces the efficiency of the volute, as the water in these side pockets lags, or probably becomes "dead."

### Proportions of the Eye and Periphery

The remarks which follow apply to all of the ordinary types of centrifugal pumps, only slight modifications being required, which will depend upon the duty of the pump.

In general, the best efficiency will be obtained when the peripheral velocity of the disk is about 0.9 $\sqrt{(2gH_m)}$ for pumps with guide vanes, and radial-exit vane tips. For pumps having plain volutes, the best peripheral speed is about 1.1 $\sqrt{(2gH_m)}$ when the vane-tip angles at exit are about 38 to 40 deg., but may be as high as 1.3 $\sqrt{(2gH_m)}$ when the angles are as small as 15 to 16 deg. The pump is only efficient at the speed and discharge for which it was designed, and since it is only possible to design for one particular speed and discharge, it is important that the pump should always be worked at that speed.

In all cases the eye of the pump must be large enough to

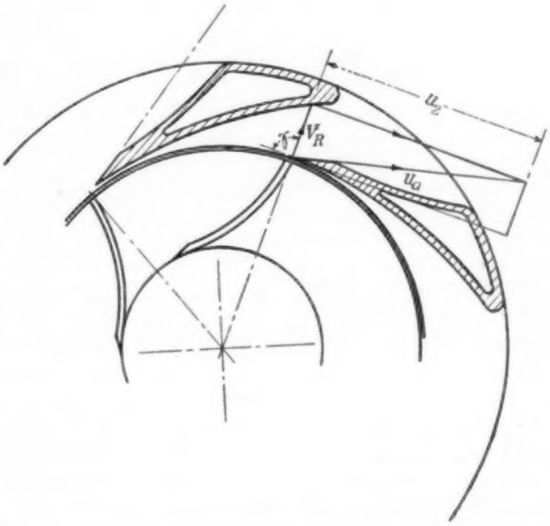

Fig. 6 Velocity Diagram for Turbine Pump Having Radial-Tip Vanes at Discharge and Guide Vane

Suitable Velocities, etc.: $u_2 = 0.9\sqrt{(2gH_T)}$
$V_R = 0.23\sqrt{(2gH_T)}$
$\gamma = 90$ deg.

allow the passage of the whole of the water at a velocity about equal to that in the suction pipe. For general purposes the diameter of the disk can be made about twice that of the eye, due regard being given to the peripheral velocity, as given above. This proportion will be found suitable for moderate speeds.

It often happens that special low speeds are required, and this often necessitates a ratio of the eye to disk as great as 1:5. A pump with which the author has had some experience was used for pumping and circulating water through a condenser, being driven direct by a small low-speed steam engine. The diameter of the eye in this case was $^1/_5$ of the peripheral diameter; approximately. Such proportions do not permit high working efficiencies to be obtained, on account of excessive disk friction: this point is, however, considered of secondary importance in these special cases.

Conversely, when high speeds of rotation are required, the diameter of the periphery may be only $1^1/_2$ times the diameter of the eye.

The deciding factor is the best peripheral speed, as given above, and therefore, with this point in view and the quantity of water to be dealt with, the disk can be proportioned. In the case of the open disk no appreciable axial movement must be allowed, while with a shrouded disk about $^1/_4$ in. on either side of the center may be allowed; this may be greater in large pumps.

### Vanes

The requisite number of vanes will depend upon the speed of the disk. For general purposes, 8 to 12 vanes will suffice, but where high speeds are to be used, 12 to 24 vanes may be necessary in order to avoid excessive slip. The whole question depends upon speed, but the majority of moderate-speed pumps have either 8 or 12 vanes; if too many are provided, the waterways become too small. The vanes should be made as thin as is conveniently possible to cast, while the same applies to the shrouding, if such is used: about $^3/_8$ in. to $^1/_2$ in. is suitable for the vanes in most cases of moderate-sized pumps, while the shrouding should not be much more than $^1/_4$ in.

### Width of Waterways

The best velocity of flow through the disk is about 0.25 $\sqrt{(2gH_m)}$, or approximately one fourth of the peripheral speed, but often lower speeds will be found practicable, particularly in the high-head single-stage pumps. To keep the speed constant, the sides of the disk should be of hyperboloidal form. This is obtained by making the product of the width of the waterway at any radius and that radius a constant quantity. In some cases the velocity of flow through the disk is not constant, the speed at exit being reduced slightly. The effect of such changes will be apparent on reference to the velocity diagram, Fig. 1, and it is a matter of individual experience as to which gives the best results. In all cases the values selected should be within the limits given. When calculating the widths of waterways, the thickness of the vanes must be taken into account.

### Vane-Tip Angles

For low lifts, say, 25 to 60 ft., an exit angle of 38 to 40 deg. is suitable, while an entry angle of 18 to 24 deg. holds for the same conditions. For lower lifts the exit angle needs reducing somewhat, the same entry angles being suitable.

In most high-lift turbine pumps, the exit vane tips are radial.

The effect of altering the exit angle will be apparent from equation $V_W = u_2 - V_R \cot \gamma$. The cotangent of an angle reduces as the angle increases, and therefore $V_W$ becomes greater as $\gamma$ is increased, and becomes nearer to $u_2$. The loss due to the impact of the water leaving the disk and meeting that flowing in the volute may therefore be exceptionally high. The manometric efficiency will also be affected.

When the angle is reduced it becomes necessary for the disk to run faster in order to pump against a given head. The result of this will be to increase disk friction, and also mechanical friction in the bearings.

For the water to enter the vanes without shock, it will be observed by referring to the velocity diagram, Fig. 1, that $\tan^{-1}(V_R/u_1) = \alpha$.

### Stresses in the Disk

The stresses in the disk are not easy to calculate; the principal stresses involved are the circumferential and the radial. The radial will be maximum at the hub, and the circumferential at the periphery. In order to reduce friction, the disk is often cut away toward the periphery. This should be done with care, and consistent with the stresses involved. (See Morley's Strength of Materials.)

The hub of the disk is important and should be made so as to provide good bearing length for the shaft. The disk should be pressed on tightly over a key, the usual drive-fit allowance being permitted.

### Bearings and Glands

The bearings of a centrifugal pump should always be of ample length; from $2^1/_2$ to $3^1/_2$ times the shaft diameter is usual. The question of having ample bearing area is important in high-speed pumps, particularly since, if too small, excessive wear will occur and the shaft will, of course, drop. This may result in the impeller's fouling the casing, especially if the clearances are slight. The ring-oiler bearing is the usual type employed, although plain solid bushes are often put in, particularly where a cheap job is desired. In all high-speed work the ring-oiler bearing is to be recommended; the solid bush bearing is, however, more convenient in the smaller pumps. With this latter type, lubrication is often effected by means of grease cups and screwed caps.

The glands necessary to prevent excessive leakage should always be bored with a slight clearance, the usual allowance being 0.015 in. The length of the stuffing boxes should be about equal to the shaft diameter, suitable neck rings also being provided.

The best packing for pump stuffing boxes is undoubtedly rawhide. With this material the shaft suffers no scoring, and rings can easily be replaced or added to the stuffing box. Square-section flax, graphited and greased, is often used, but often to the detriment of the shaft.

### Priming Apparatus

An important point to consider in the design of the pump is the position in which it is to work. Before pumping will commence, the pump and suction pipes must be full of the liquid to be pumped. This necessitates its either being "drowned," or some means provided to exhaust the air and vapor. It is not always possible or desirable to work a pump "drowned," and, generally speaking, some auxiliary apparatus must be provided to prime the pump.

There are three methods in general use, which may be denominated as follows:

*a* Steam ejectors
*b* Vacuum pump, and
*c* Foot valve and filler.

In some cases automatic contrivances are employed.

Method *b* is usually most convenient, and in small installations a hand pump will suffice, while method *c* is also suitable for small plants. These two methods are often employed unless the pump happens to be located near or within easy reach of a steam supply. In such cases the first method would perhaps be desirable.

Small oil pumps, and circulating pumps for cooling water in internal-combustion-engine work, are usually located in such a position that they always remain full, or in some cases are completely "drowned."

The foot valve and filler method, although convenient in many ways, is often very unsatisfactory, particularly so if gritty or sandy material is to be pumped. Small particles get underneath the valves and leakage takes place, with the result that the filling of the pump becomes difficult, if not impossible. If such valves are used, a screen must always be provided to prevent, as much as possible, the occurrence of the trouble mentioned.

### Valves

Immediately next to the pump, and on the delivery side, a sluice or check valve must always be provided. This becomes necessary to prevent water rushing down the delivery pipe during priming, and either smashing the impeller or bursting the pump.

Sluice valves with wheel and screw can be hand operated when the size does not exceed 20 in. Larger sizes require

gearing, while in exceptional cases hydraulic or other power may be required.

### Materials of Construction

For such purposes as the pumping of water and oil, cast iron is usually employed for the casings of centrifugal pumps, a good-quality, close-grained material giving excellent results. For such purposes as dredging, or the pumping of gritty water, and in fact in all cases where solid material passes through the pump, special precautions are necessary. The wear on the casing, and also on the impeller, in such cases is very severe, and cast steel may be required. The cost of such is great, and generally special linings of manganese steel are inserted, or, as in some cases, chilled castings are employed.

Small pumps are often made entirely of bronze or a cheap gun metal.

For such purposes as the pumping of acids, again special material must be used. In such cases, an acid-resisting material must be used, there being several alloys on the market which more or less fulfil the condition.

The disks of pumps are often made of good-quality, close-grained cast iron, and are painted and varnished after being machined. Some manufacturers, however, use good-quality bronze for their disks and machine them all over; painting in this case is not necessary.

In the special cases mentioned, cast steel is very often used, since hard wear is obtained with this material, which is of course essential where solid matter has to be dealt with.

For the shaft, mild steel is suitable, having an ultimate tensile strength of 28 to 30 tons. The stress carried by the shaft is not usually severe, the loading being fairly constant. In the case of high-speed pumps the shaft should run in gun-metal brasses provided with white-metal pockets or white-metal linings. Solid gun-metal bushes are suitable for small and lower-speed pumps. To prevent corrosion of shafts, brass protecting sleeves are fitted.

## Discussion

I. E. Moultrop.[4] Many valuable data of interest to pump designers have been presented in the three papers on centrifugal pumps.[5] I should think that these studies should help the pump designers to determine the characteristics of pumps at all capacities before they are built.

I should like to say a word in reference to centrifugal pumps from the standpoint of the purchaser and operator of such pumps.

During the past few years more attention has been paid to testing the pumps after installation than heretofore. This is proper because the size of the pumps has been increasing by leaps and bounds, and the kilowatt-hours consumed by the motors that drive the pumps have become a matter of major importance to the users of centrifugal pumps.

These tests have developed the fact that the pumps in operation in many cases have decidedly different characteristics from those expected. In many cases they fail to meet the guaranteed head, capacity, and efficiency, and even more often fail to show the expected characteristic curves from zero to full capacity.

The pump designers should realize that it is no longer satisfactory for a centrifugal pump to meet its guarantees at one particular capacity. What the purchaser needs are the complete characteristic curves, and the manufacturer should bend every effort to bring about the time when he can guarantee that the pump will perform in accordance with the characteristic curves at all capacities.

We now have installed boiler-feed pumps requiring approximately 2600 hp. to drive them. Before such pumps are installed the controllers must be designed. It is impossible to properly design the controllers unless the characteristics of the pumps are known.

We are not "out of the woods" in the case of any of the major pumps in a steam-electric generating station.

From the standpoint of the purchaser and operator of centrifugal pumps I would urge the pump manufacturers to intensively study the problem so that they can guarantee the pumps at all capacities within reasonable limits. Larger and larger pumps are being needed to keep step with the continually increasing size of turbine and boiler units. I realize that the pump manufacturers have a big problem, but it is up to them to solve it. The users of their pumps are willing to help as much as possible.

[4] Chief Engineer, The Edison Electric Illuminating Co., Boston, Mass. Mem. A.S.M.E.

[5] This discussion applies also to the papers by M. D. Aisenstein and Joseph Lichtenstein on the same subject. See papers HYD-50-1 and -2.

W. M. White.[6] The paper is inaccurate, in that the impeller in Fig. 6 should be turned in the opposite direction. Otherwise it cannot direct the water into the channels provided. The author further says that centrifugal pumps having guide vanes in the discharge are the most efficient type. The writer cannot agree with this statement. In the light of modern American practice it is not correct.

The Author. The author thanks Mr. Moultrop for his opening remarks. With regard to the difficulties of pump users or prospective ones, the author has no doubt that these problems are being faced by pump manufacturers seriously and that more and more information is becoming available almost daily.

In reply to Mr. White's first remark, the author regrets that due to oversight the impeller portion of the drawing was allowed to go forward badly drawn. The direction of motion of the impeller is intended to be clockwise, and the vane tips radial at exit. In regard to the second point raised, some misunderstanding surely prevails. If, say, for a head of 250 ft. a guide-vane pump is provided and the quantity of water to be handled is fairly small, then it will give a higher efficiency than a volute pump in the same service. In all cases where a high velocity of discharge from the disk occurs and when the head is great, some means must be provided to convert a maximum of the kinetic energy of the water at discharge from the disk pressure energy. Guide vanes are common for this purpose, and in addition in multi-stage pumps they provide a guide from the outlet of one wheel to the eye of the next. The statement referred to was intended to apply to turbine pumps dealing with high heads and running at high speed. These machines, when carefully designed, undoubtedly give very high efficiency.

HYD-50-5

# Computation of the Tail-Water Depth of the Hydraulic Jump in Sloping Flumes

BY ROBERT W. ELLMS,[1] CLEVELAND, OHIO

*This investigation deals primarily with the methods of computing the tail-water depth of the hydraulic jump when it is produced in sloping flumes. The author has developed two formulas for this calculation based upon the unpublished work of A. G. Levy and J. W. Ellms of the Cleveland Water Department, and of J. R. Fleming and the author in a thesis presented to Case School of Applied Science. In this paper are given a description and the data of the latter's thesis work, and certain data obtained by the two former investigators. From a study of the results of these experiments the author has drawn certain conclusions as to what takes place in the hydraulic jump when it is produced in sloping flumes, and attempts an explanation of this spectacular and baffling phenomenon.*

The hydraulic jump is generally described as the turbulent passage of water from a high velocity and low depth to a much greater depth and with a corresponding decrease in velocity. The jump may occur under suitable conditions in nature, such as on the shores of the ocean, or of large lakes, or in streams, and may be artificially produced at the foot of dams and in specially constructed flumes. Probably the first recorded studies of this phenomenon were made by Bidone in 1819, and published in the Transactions of the Royal Societies of Turin. Later investigators include Gibson, Ferriday, Lane, Kennison, Hines, Riegel, Beebe, and Levy and Ellms. The four latter investigators, R. M. Riegel and J. C. Beebe of the Miami Conservancy District, and A. G. Levy and J. W. Ellms of the Cleveland Water Department, experimented with sloping and expanding flumes, while all the previous investigators used practically level flumes of constant cross-sectional area.

The experiments conducted by the Miami Conservancy District were to determine what type of flume construction would insure the occurrence of the hydraulic jump in the flood run-off water leaving large retarding basins placed beside the Miami River. The excess kinetic energy in the water was to be dissipated in the hydraulic jump, which was produced just below restricted dam outlets. J. W. Ellms of the Cleveland Water Department conceived the idea of using the turbulent action of the jump for the mixing of chemical solutions with the water to be treated in water-purification processes, and with A. G. Levy he conducted experiments in 1920 with a large experimental flume. Their object was to design a flume which would properly control the jump with the expenditure of a minimum amount of energy, while still maintaining a satisfactory mixing action. In this process it became very important to accurately compute the surface curve of the water both before and after the jump, in order to determine the minimum loss of head under which the jump could operate. The surface curve up-stream from the point of jump was readily computed by the application of Bernoulli's theorem, but it was the failure of the classical momentum formula to give the correct depth of tail water when applied to a jump produced in a sloping flume that led to the investigation of several slopes by J. R. Fleming and the author in May, 1927. The object of this investigation was to discover a possible relation between the slope of a flume in which the hydraulic jump was being produced, and the depth of tail water. The results of this work appeared to be so satisfactory as to warrant the belief that they would be of general interest to hydraulic engineers.

## Description of Experimental Apparatus

The work conducted by J. R. Fleming and the author was carried out at the Baldwin Filtration Plant in Cleveland, Ohio. The supply of water was taken from a high-pressure main, controlled by a four-inch valve, passed through a water meter, and then into a large wooden head tank, and into which the throat of the flume was built. The expanding wooden flume was made of $^3/_4$-in. matched lumber, and had a maximum capacity of 1.5 c.f.s. (cu. ft. per sec.). It was attached to the protruding end of the throat as shown in Fig. 1, and so constructed as to make a flexible joint at $A$, which enabled the slope to be varied from 0.15 ft. per ft. to 0.30 ft. per ft. Weir boards and an adjustable gate, controlled by a hand screw, were located at the down-stream end of the flume for the purpose of controlling the tail-water depth. A wooden chute was placed at the discharge end of the flume to receive the water and carry it to the sewer. The detailed dimensions of the flume are shown in the plan and elevation drawings of Fig. 1.

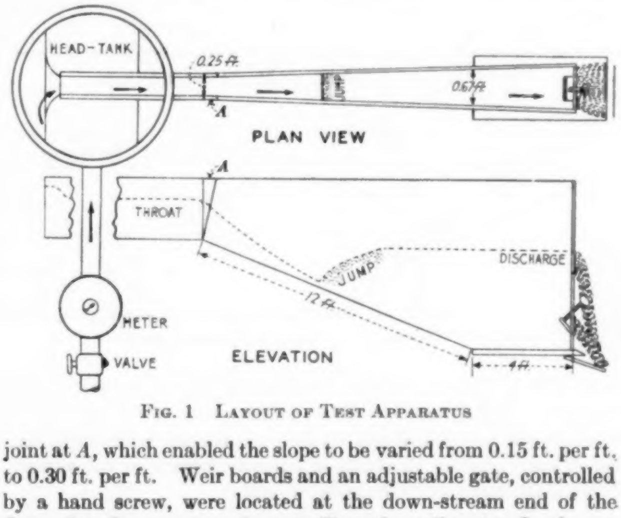

FIG. 1 LAYOUT OF TEST APPARATUS

## Method of Procedure

The slope of the flume was first established with the aid of a level and leveling rod, and then a reference line, obtained by filling the flume with water, was drawn on an inside wall. The elevation of this reference line from station No. 7 was determined and all tail-water depth measurements were referred to it. Station No. 1 was located at the throat. On the bottom of the flume, heavy black lines were drawn at right angles to the line of flow, and spaced at two-foot intervals, marking the positions of stations Nos. 2, 3, 4, 5, 6, and 7, respectively. The quantity and rate of flow of the water were measured by an accurately calibrated water meter and stop watch. The depth of tail water was regulated by the addition or removal of weir boards at the discharge end of the flume, and a finer adjustment obtained by a gate which could be operated by a hand screw.

The jump was made to occur at a given station and the tail-water depth was then measured from the reference line by means of a steel scale which was lowered into the flume until it just

[1] Jun. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Spring Meeting, Pittsburgh, Pa., May 14 to 17, 1928, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

touched the surface of the water. This was done for quantities of 1.0 c.f.s. and 1.5 c.f.s., and with slopes of 0.22 and 0.30 ft. per ft., and with the jump taking place at the stations and mid-stations listed above.

### Hydraulic-Jump Computations

The water issuing from the head tank and passing into the throat drops to the critical depth, the value of which may be determined by the formula

$$d_c = \sqrt[3]{\frac{Q^2}{gb^2}}$$

in which $d_c$ = critical depth in ft.
$Q$ = quantity in c.f.s.
$b$ = width of throat in ft.
$g$ = acceleration due to gravity.

The surface curve down the slope may be calculated by equating the change of energy from one station to the next to the

Fig. 2 Hydraulic Jump in Horizontal Flume

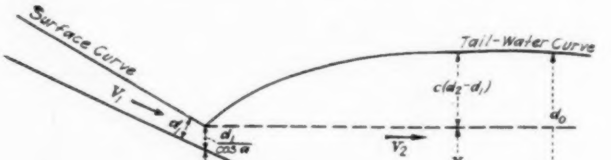

Fig. 3 Hydraulic Jump in Sloping Flume

head lost in friction between stations, as stated by the Chézy formula. This involves a rather tedious cut-and-try process to solve for the new depth and velocity at each succeeding station; but when carefully executed, accurately computes the surface curve of the water up to the point of jump.

When the jump takes place in a horizontal flume, the tail-water depth may be calculated by equating impulse to change of momentum.

In Fig. 2, let $d_1$ = depth of stream entering hydraulic jump
$d_2$ = depth of stream following hydraulic jump
$V_1$ = velocity of stream entering hydraulic jump
$V_2$ = velocity of stream following hydraulic jump.

The change of momentum equals $(wQ/g)(V_1 - V_2)$, and the impulse producing this change of momentum equals $\frac{w}{2}(d_2^2 - d_1^2)$, in which $Q$ is the quantity in cubic feet per second per unit width of stream, and $w$ equals the unit weight of water flowing. Equating impulse to change of momentum and solving for $d_2$ gives

$$d_2 = \sqrt{\frac{2V_1^2 d_1}{g} + \frac{d_1^2}{4}} - \frac{d_1}{2} \quad \text{[1]}$$

This formula gives a value for the depth of tail water which is much too great when the jump is made to take place in a sloping flume, and plainly shows the need for a special formula. New derivations of Equation [1] were sought, using the change-of-momentum principle as applied to a sloping flume, and in every case an indeterminate equation resulted. After numerous attempts to discover a correct combination of the velocity, the elevation of the station before the jump, and the depth of water before and after the jump, which would have some definite and constant relation to the slope, it was finally observed that

$$\frac{d_0 - z - \dfrac{d_1}{\cos a}}{d_2 - d_1} = f(\sin a) \quad \text{[2]}$$

In the above Equation [2] and Fig. 3, let

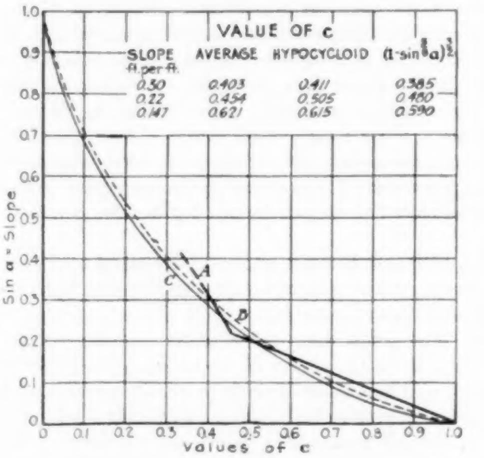

Fig. 4 Plotting of $f$ (sin $a$) for Equation [2]

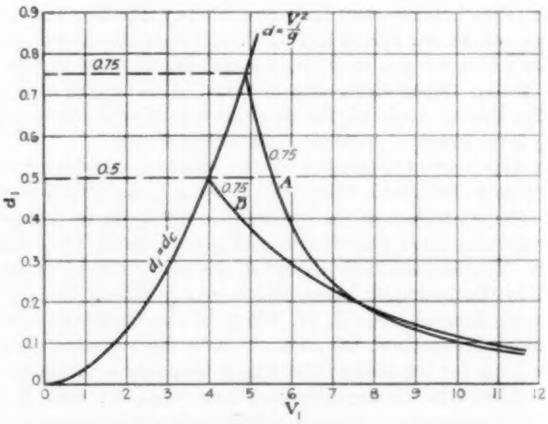

Fig. 5 Corrected Momentum Formula for Sloping Flume
Curve A = $d_2$ according to the momentum formula.
Curve B = $d'_2$ in sloping flume referred to a horizontal condition.

$d_0$ = observed depth of tail water
$d_1$ = depth of water measured normal to the bottom of the flume before the jump
$d_2$ = depth of tail water as calculated by Equation [1] for the same $V_1$ and $d_1$
$a$ = angle which the flume makes with the horizontal
$z$ = elevation of the station at which the jump takes place
$Y_1 = z + \dfrac{d_1}{\cos a}$
$j$ = $d_2 - d_1$ and $c(d_2 - d_1) = cj$, where $c$ equals the constant sought.

After plotting sin $a$ against $c$ it was noted that a curve through these points followed the general form of a modified hypocycloid of four cusps, the equation of which is $x^{2/3} + y^{2/3} = k^{2/3}$. Substituting $k = 1$, $x = c$, and $y = \sin a$ gives

$$c^{2/3} + (\sin a)^{5/3} = 1^{2/3}$$
$$c^{2/3} = 1 - (\sin a)^{5/3}$$
$$c = [1 - (\sin a)^{5/3}]^{3/2}$$

The final tail-water depth equation may be derived by substituting the value of $c$ for $f$ ($\sin a$) in Equation [2].

$$\text{Thus } \frac{d_0 - z - \dfrac{d_1}{\cos a}}{d_2 - d_1} = [1 - (\sin a^{5/3})]^{3/2}, \text{ and}$$

$$d_0 = [1 - (\sin a)^{5/3}]^{3/2} (d_2 - d_1) + \frac{d_1}{\cos a} + z, \text{ or}$$

the complete equation for $d_0$ in terms of $d_1$, $V_1$, $z$, and the angle $a$ of the flume becomes

$$d_0 = [1 - (\sin a)^{5/3}]^{3/2} \times \left[\sqrt{\frac{2d_1V_1^2}{g} + \frac{d_1^2}{4}} - \frac{3}{2} d_1\right] + \frac{d_1}{\cos a} + z \ldots [3]$$

The calculated tail-water depths given by Equation [3] are listed in Tables 1 and 2 in the next column.

Column $D$ of these tables shows the computed values of $f$ ($\sin a$) in Equation [2], as determined from the observed data. Curve $A$ of Fig. 4 shows the plotting of the average value of $f$ ($\sin a$) for each of the three slopes. Curve $B$ is the curve of the pure hypocycloid, while Curve $C$ is that of the modified hypocycloid. The reason for changing the exponent of $\sin a$ from $^2/_3$ to $^5/_3$ was to bend the curve down lower and thus make it pass through the more likely average of the observed data plottings.

While the depth of tail water as computed by Equation [3] is in excellent agreement with the observed depth for the large majority of cases, there is a marked deviation in the calculated depth of tail water by this formula when the values of $d_1$ and $V_1$ are near the critical depth and critical velocity. In some unpublished data of Levy and Ellms, given in Table 2, the $d_0$ as computed by Equation [3] gives values that are much too low when the jump is made to take place near the throat, or when the water is flowing near its critical depth and critical velocity. This tendency may be observed for the three rates of flow with which they experimented. The value of $c$ exceeds unity in at least two cases, which means that the water actually jumped higher on the slope than the impulse formula alone would give for a flume in the horizontal position. It seemed that the error lay in the use of the momentum formula [1] in the derivation of Equation [3]. That is, a new formula for $d_2$ which would give a better agreement with $d_0$ in formula [3], when the water was flowing just below the critical depth, was looked for as a substitute for the classical momentum formula. This analytical study of the data and formulas was carried on after the presentation of the thesis.

When water is flowing at its critical depth and critical velocity in a horizontal flume of constant width, an increase in depth would mean an increase in energy. If the water is flowing at its critical depth into a sloping flume and an increase in section is produced, such that the final depth approaches infinity and the velocity approaches zero, the entire surface curve may be accurately computed by the application of Bernoulli's theorem. In this case, for all practical purposes, the increase in depth measured from the point at which the change of section takes place, is equal to $^3/_2\, d_c$. On this assumption, the depth of water after the jump

Above data from unpublished work of Levy and Ellms computed by Equations [3] and [8].

* These values omitted from averages.

or change of section, referred to the horizontal case, was drawn as shown by Curve $B$ of Fig. 5. The problem was to determine the equation of Curve $B$.

Assuming $d_1 = d_c$, then $d'_2 = {^3/_2}\, d_c$ or $^3/_2 d_1$, as noted in Fig. 5. If the velocity was increased while $d_1$ remained constant, it was observed that $d'_2 - {^3/_2}\, d_1$ increased directly in proportion to the change of velocity.

Thus

$$\frac{\left(d'_2 - \frac{3}{2}d_1\right)}{V_1 - V_c} = f(d_1) \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

Letting $V_c = \sqrt{gd_1}$, and solving for $d'_2$ gives

$$d'_2 = \frac{3}{2}d_1 + f(d_1)(V_1 - \sqrt{gd_1}) \quad \ldots\ldots\ldots\ldots [5]$$

Taking a series of values for $d_1$ and $V_1$, and $d'_2$ as read from a system of curves similar to Curve $B$ of Fig. 5, and plotting a new curve in order to determine the relation between $d_1$ and the value of the function, Curve $A$ of Fig. 6 was drawn. Owing to the difficulty of determining the equation of Curve $A$, the value of the function of $d_1$ was plotted against the critical velocity $V_c$ corresponding to the critical depth. The result of this plotting is Curve $B$ of Fig. 6 which is virtually a straight line, and for which the equation may be readily determined. Thus

$$f(d_1) = K\sqrt{gd_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

in which $K$ equals the slope of Curve $B$.

The final equation of Curve $B$ of Fig. 5 is therefore

$$d'_2 = \frac{3}{2}d_1 + K\sqrt{gd_1}(V_1 - \sqrt{gd_1}) \quad \ldots\ldots\ldots [7]$$

which gives the theoretical height of jump for a sloping flume referred to the horizontal position.

Since the final formula for $d_0$ as given in the form of Equation [3] would have two empirical constants in it, when Equation [7] was substituted for the momentum formula it was thought best to use the pure hypocycloid for $f$ (sin $a$), or $c$, instead of the modified form. This equation may finally be written,

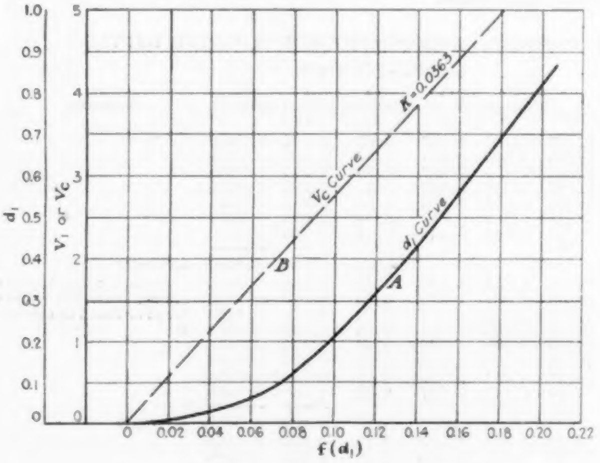

FIG. 6 VALUE OF $f(d_1)$ IN EQUATION [5]

$$d_0 = (1 - \sin^{2/3} a)^{3/2}\left[K\sqrt{gd_1}(V_1 - \sqrt{gd_1}) + \frac{d_1}{2}\right] + \frac{d_1}{\cos a} + z \quad \ldots\ldots [8]$$

From this equation $K$ was computed from all of the available data for each of the three slopes, and the average found to be 0.0363. The depths of tail water as computed by Equation [8] for each case are also listed in Tables 1 and 2 and show a most satisfactory agreement with the observed measurements.

It became apparent that the formula for $d'_2$ was simply $d_2 + \frac{V_2^2 - V_0^2}{2g}$. In other words, an increased cross-section decreases the velocity, with a consequent gain in the static head. This value must be added to the value for $d_2$ as calculated by the momentum formula in order to obtain the true value of $d'_2$ in a sloping and expanding flume. In formula [8], $d'_2 = 0.0363\sqrt{gd_1} \times (V_1 - \sqrt{gd_1}) + {}^3/_2\, d_1$, the value 0.0363 is the average for the two flumes in which experiments were made, and for the quantities of water used in each. The form $d_2 + \frac{V_2^2 - V_0^2}{2g}$ is not dependent on observational data, since it has *no empirical constants*. The value of $V_0$ is always very small and may usually be neglected. When in doubt as to its value, the formula should be solved by the cut-and-try method. $V_2$ equals $\frac{d_1V_1}{d_2}$.

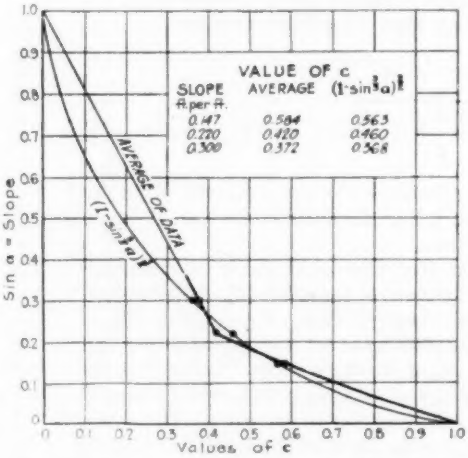

FIG. 7 PLOTTING OF $f$ (SIN $a$) AND $c$ FOR EQUATION [9]

Putting the new value for $d_2'$ in formula [8] gives

$$d_0 = \left(d_2 + \frac{V_2^2 - V_0^2}{2g} - d_1\right)c + Y_1 \quad \ldots\ldots\ldots [9]$$

This form of the equation has but one empirical constant for each particular slope. The average value of $c$ was computed from the data for each slope and found to be as follows:

| Slope, ft. per ft. | Value of $c$ |
|---|---|
| 0.147 | 0.584 |
| 0.220 | 0:420 |
| 0.300 | 0.372 |

The exponent ${}^2/_3$ of sin $a$ in the hypocycloid was changed to ${}^3/_4$, and the resulting function gave values of $c$ for each slope which compared favorably with the above averages; thus

| Slope, ft. per ft. | $(1 - \sin^{3/4} a)^{3/2}$ |
|---|---|
| 0.147 | 0.563 |
| 0.220 | 0.460 |
| 0.300 | 0.368 |

Fig. 7 shows the average curve and the second modification of the hypocycloid. The third general formula for the computation of the tail-water depth for the hydraulic jump, when produced in sloping and expanding flumes, may then be written as follows:

$$d_0 = \left[\sqrt{\frac{2V_1^2d_1}{g} + \frac{d_1^2}{4}} - \frac{3d_1}{2} + \frac{\left(\frac{d_1V_1}{d_2}\right)^2 - V_0^2}{2g}\right] \times (1 - \sin^{3/4} a)^{3/2} + \frac{d_1}{\cos a} + z \quad \ldots [10]$$

Accordingly, all runs were computed using this formula and the results checked almost exactly in every case with those as computed by Equation [8]. For this reason, it was not thought necessary to repeat the tables.

### Discussion and Conclusions

The problem involved was to find a combination of the depth and velocity of water before the jump, and the slope of the flume, and their relation to the tail-water depth. Many combinations

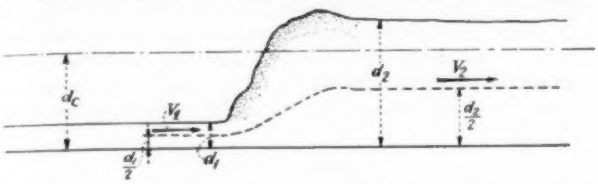

Fig. 8 Hydraulic Jump in Horizontal Flume Showing Rise in Center of Mass

were tried, such as $\frac{d_0 - z - d_1}{d_2} = f(\sin a)$, or $\frac{d_0 - z}{d_2 - d_1} = f(\sin a)$, or simply $\frac{d_0 - z}{d_2} = f$ (sin $a$), and all proved unsatisfactory, the reason being that the ratio $d_2/d_1 = J$ had to be taken into account. The formulas finally developed eliminate the effect of $J$ by subtraction. It was observed that a coefficient taking the form $(1 - k \sin a)$ times the $d_2$ for the horizontal condition, plus $Y_1$, also varied with a change of $J$. Fair agreement with observed depths of $d_0$ were obtained with this equation for an average value of $k = 2.22$. However, these results had to be modified too much for extreme values of $J$, and a more constant relation was looked for.

From Curve $A$ of Fig. 4 the relation $\dfrac{d_0 - z - \dfrac{d_1}{\cos a}}{d_2 - d_1}$ was found to be much more constant in its variation with the variable $\sin a$. A rough test for angles greater than 20 deg. indicated that the value of $f$ (sin $a$) approached zero as sin $a$ approached unity. This fact indicated that $c$ had no appreciable value when the angle was 90 deg. The term $d_1/\cos a$ corrects $d_1$ for a sloping flume, and it can be readily seen that for small values of $a$, this term is nearly equal to $d_1$. As the angle increases $\cos a$ decreases, approaching zero, with the result that this term becomes infinite.

Since Equation [3] did not hold strictly for computed tail-water depths when the water was flowing at or slightly below the critical depth, Equations [8] and [10] were developed and found to give a closer agreement with all observed results. For all practical purposes any of the three Equations [3], [8], and [10] may be used, as brought out by a study of columns $A$, $B$, and $C$ in the tables. Equation [8] is much simpler to use because with a fixed slope the formula may be reduced to one of three terms. For example, with a slope of 0.30 ft. per ft. of slope, where the value of $c$ is 0.411, the equation becomes

$$d_0 = 0.411 \left[ 0.0363 \sqrt{gd_1}\,(V_1 - \sqrt{gd_1}) + \frac{d_1}{2} \right] + Y_1$$

which finally reduces to

$$d_0 = 0.0843 V_1 \sqrt{d_1} - 0.273\, d_1 + Y_1$$

Equation [10] should really be solved by the cut-and-try process, because the actual velocity of the tail water is dependent on the depth $d_0$ and the width of the flume. The term $\frac{V_2^2 - V_0^2}{2g}$ corrects exactly for the change of section and adapts itself to the particular flume used. Thus formula [10] is complete, since it takes care of the change of momentum by the $d_2$ formula, change of section by the velocity term, change of slope by the modified hypocycloid equation, position in the flume by the $z$ term, and the correction of $d_1$ for the angle of the flume. The loss of head due to friction in turbulent water was considered to be so small that it could be neglected in all the formulas developed.

The only data available for the development of these formulas have been for flumes having slopes of 0.147, 0.22, and 0.30 ft. per ft. of slope, respectively. After more data have been obtained for wider ranges of depth, velocity, and slope, it may result in some modification of these formulas, but it is believed that their general form will hold. Hydraulic measurements in rapidly flowing and turbulent water are necessarily open to observational errors, which are reflected in constants of empirically developed formulas of this type. It is, however, rather gratifying to note that the developed formulas hold with a surprisingly small percentage of error for quantities ranging from 1.0 to 40.0 c.f.s.

The production of the hydraulic jump in sloping flumes has led the author to attempt an analysis of this phenomenon, based partly upon the mathematical deductions presented in this paper and partly upon an observational study of the jump in an experimental flume. The following discussion deals with flumes of constant width only.

The accepted definition of the hydraulic jump is the turbulent passage of water from a depth below the critical depth to an alternate momentum stage above the critical depth. The water dissipates a large part of its kinetic energy in passing from the lower to the alternative or upper stage through the turbulent action produced, and probably through much internal impact. When the jump is produced in a practically horizontal flume, the center of mass of the water is raised as shown by the dotted line in Fig. 8. It is this increase in potential energy that gave to the phenomenon

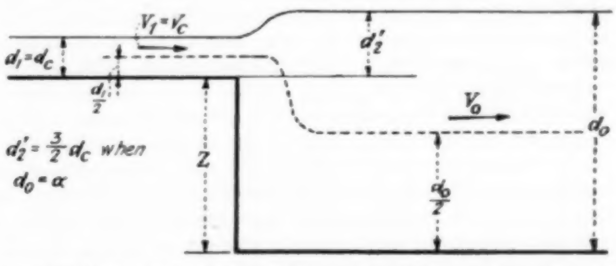

Fig. 9 Effect of Change of Section for Water Flowing at or Above the Critical Depth

the name of the hydraulic jump. The water moving at a high velocity below the critical depth must have the interposition of an outside force upon it in order to make it flow at the greater depth.

An interesting condition arises, however, when the water is made to flow at the critical depth and into a large body of water, as shown in Fig. 9. The rise in the surface of the water is not accompanied by any turbulent action. The center of mass lowers instead of rises, and no jump is produced. The surface curve may be readily computed by the application of Bernoulli's theorem. Formulas [8]. and [10] may be used to compute $d_0$. In this case the depth $d'_2$ is increased simply as a result of the increased section.

If the water flows below the critical depth under conditions similar to those illustrated in Fig. 9, a much more complicated condition arises. When the change of section is such that the velocity of the tail water is greatly reduced, and a jump is produced at this change of section, there exists a combination of the two effects diagrammatically represented by Figs. 8 and 9. Such a combination is shown in Fig. 10 Here the center of mass

lowers and still a "jump" is produced. Mathematical calculations for the value $d'_2$ must be corrected for impact and change of section. Formulas [8] and [10] reduce in the following manner:

$$d_0 = (d'_2 - d_1)(1 - \sin^n a)^{3/2} + \frac{d_1}{\cos a} + z$$

Since $a$ equals zero, $\sin a$ equals zero and $(1 - 0^n)^{3/2} = 1$, and

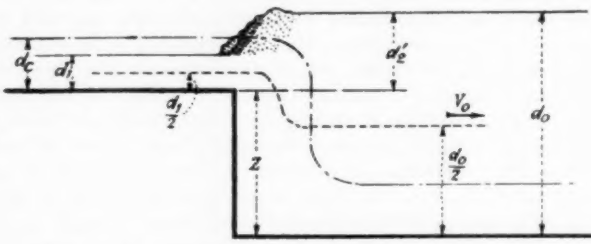

FIG. 10 COMBINATION OF JUMP AND CHANGE OF SECTION

$$d_0 = (d'_2 - d_1)\,1 + \frac{d_1}{1} + z = d'_2 + z$$

Formula [8] gives $d'_2 = 0.0363\sqrt{gd_1}\,(V_1 - \sqrt{gd_1}) + \frac{3}{2}d_1$

Formula [10] gives $d'_2 = d_2 + \frac{V_2^2 - V_0^2}{2g}$

For formula [10] $d_2'$ is found by the cut-and-try method, and friction is neglected. The value $d_2'$ corrects for impact and the velocity term corrects for the change of section. If $z = 0$, $V_0 = V_2$ and $d_2' = d_2$. That is, the conditions are identical with those shown in Fig. 8.

The tail-water depth computation becomes still more complicated when the jump is produced in a sloping flume. Here we have the water before the jump flowing below the critical depth and at some angle $a$ with the horizontal. This angular impact reduces the value of $d_2'$. That is, the value $d_2'$ is less than it would be were the flume in a horizontal position. The exact path of the center of mass in the turbulent portion of the jump is indefinite, because the surface curve from which it is determined is indefinite. These conditions are illustrated in Fig. 11. If $z$ has an appreciable value, the tail-water velocity is reduced, and therefore $d_2'$ will be slightly increased. In the development of the formulas it was found necessary to subtract

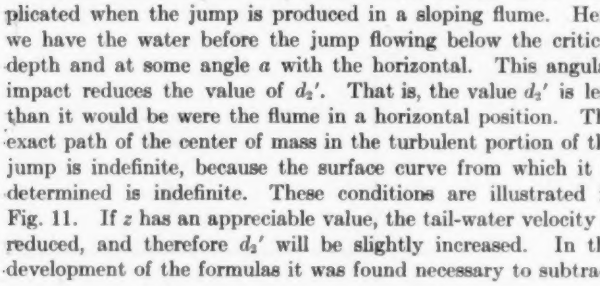

FIG. 11 HYDRAULIC JUMP IN SLOPING FLUME SHOWING PATH OF CENTER OF MASS

$d_1$ from $d_2'$ before multiplying by the hypocycloid term. The values $d_2 - d_1 = j$, and $d_2' - d_1 = j'$, appear more significant than the $d_2$ or $d_2'$ distances, and were used in the development of all three formulas, because they varied so regularly with a change of slope. The modified equation of the hypocycloid corrects the $d_2'$ distance for a sloping flume. Many more data will have to be compiled before it can be said that for any one slope $c$ is *exactly* constant. A slight fluctuation is observed, the magnitude of which is about the same as that due to observational error. Only a slight deviation is observed in the data, and this may be due partly to errors in flume construction or partly to the effect of friction.

In general, formula [10] is complete and has been checked by a wide range of flume conditions and flow conditions. The curve of the modified hypocycloid does not quite fit the data obtained as shown in Fig. 7, but until more slopes are experimented with it is not possible to verify the exact curvature of this line. While work will logically proceed from Equation [10], the author believes that eventually a general equation, void of any empirical constants, may be developed in some such way as the momentum formula was derived, and which will effectually bridge the gap between successive transitional back-water curves where impact is present.

# Discussion

A. G. LEVY.[2] The author deserves much credit for the excellent way in which he has analyzed the phenomenon of the jump itself as well as the mathematics involved in the derivation of the several formulas and coefficients entering therein. The paper is a fine contribution to a field of hydraulics in which little has heretofore been accomplished.

In a report[3] by J. W. Ellms and the writer an attempt was made to locate the position of the jump on a sloping, expanding flume, under a definite set of conditions, by the introduction of coefficients varying with the velocities before the jump. These coefficients are of course applicable only to conditions comparable to those under which they were obtained. As limited as this method is, it furnished, so far as the writer knows, the only means for locating the jump on a sloping, expanding flume previous to the derivations of the formulas obtained by the author of this paper. Other engineers who had had occasion to investigate problems of this nature had merely concluded that for a given depth of tail water the jump invariably occurred higher up the slope than the momentum formula indicated. The lack of any method for locating the jump in a sloping flume makes this particular paper all the more valuable.

It seems to the writer that, as the author himself states, his Equation [10] contains all the essential elements entering into a right solution of the problem, with the possible exception of the factor of friction. Inasmuch as friction is acting over a relatively short distance between $d_1$ and $d_0$, during which time the velocity is rapidly being reduced, it is not believed that that particular loss can have very much influence on the value of the coefficients obtained and therefore on the general applicability of the formula. It is of course possible that with very large flows under very high velocities, in which the distance between $d_1$ and $d_0$ increases, friction may play a more important part than is now evident. The author's analysis, however, covers a fairly wide range of quantities, and if this factor were appreciable under conditions

[3] "Report on Experiments Made with the Hydraulic Jump as a Means by which Chemicals May Be Mixed with Water to Effect Its Purification," by J. W. Ellms and A. G. Levy.

of velocity changes greater than those analyzed, it would seem that it would be more manifest now than it apparently is.

While Equation [10] seems to the writer to be the most complete of the three, it is his opinion that Equation [8] is the most practical. The necessity for a cut-and-try method with the use of Equation [10] in which $d_0$ must be known before $V_0$ can be obtained is apt to arouse considerable mental opposition, particularly as the value of $d_0$ is not known beforehand, even approximately. In the writer's judgment Equation [8] will be the more generally employed, serving at least as a basis for all preliminary studies, with Equation [10] being used only as a final check.

It would be an excellent idea if someone could develop a formula which would "effectually bridge the gap between successive transitional backwater curves where impact is present," provided that such a formula did not become too complicated for practical use. From the possible combinations of elements that might enter such a problem, the writer is not too optimistic of its success and believes that such a formula has its place in the realm of pure mathematics rather than in that of practical hydraulics. Feeling that way, he is all the more appreciative of what has been accomplished and believes that the author has laid the foundation in his Equation [10] wherein all that is necessary is for future experimenters to confirm or modify his coefficients in connection with experimental conditions other than those which the author himself has studied.

L. F. Harza.[4] Without checking over all of the author's paper or the formulas derived, the writer has observed one assumption which is believed to be a fundamental error in the author's hypothesis for deriving his formulas. He has assumed the elevation of the center of mass of the water as a measure of its potential energy. I was taught to consider the surface elevation.

Bernoulli's theorem states that, neglecting losses, the sum of potential and kinetic energy in flowing water remains constant. The energy of any infinitesimal element of flowing water at any point consists of three items, energy of elevation, energy of pressure, and kinetic energy, the two former being in the nature of potential energy. The energy of elevation represented by the elevation of the element above any assumed datum, plus the pressure energy, represented by the depth of the element below the water surface, plus the kinetic energy $V^2/2g$, is constant.

The energy of elevation plus the pressure energy represents the total potential energy and is always equivalent to the elevation of the water surface above the datum. The potential energy is therefore equal to the elevation of the water surface rather than of its center of gravity. Likewise, in any conversion of potential to kinetic energy or vice versa, the change in elevation of the water surface, neglecting losses, should be equivalent to the change in $V^2/2g$.

This principle is so fundamental to all hydraulics that its truth or fallacy should be determined before a discussion of any of the remainder of the paper is in order.

B. F. Groat.[5] I note two points that might be mentioned: In most cases I think we must arrive at the forms of our equations by the indications of mechanics and mathematics, and not by the forms of plottings unless supported by theory, although there may be some exceptions. It is certainly wrong to determine the potential energy of flowing water, where the surface level is maintained by the flow, by reference to the center of gravity of the prism of water, upstream, downstream, or at any section. This has been a common mistake in the past and seems to have had some patronage in the paper.

L. F. Moody.[6] This paper strikes me as being of considerable interest. I think it would make an excellent research subject for graduate students in colleges or some of the hydraulic research laboratories. It involves hydraulic laws applying to flow in general, and it is a subject that can rather easily be handled experimentally with comparatively simple equipment.

One point that I question is the use of the dotted center line, shown in Figs. 3, 8, 9, 10, and 11, marked "path of center of mass." It seems to me that this center-of-mass position is not the significant thing and should not be used for the basis of distinction between the various phenomena, because the position of the center of mass, which is here merely the center of area of the flow, does not determine the potential energy, but only the elevation of the center of the section. The potential energy is determined by this elevation plus the intensity of hydrostatic pressure head at that point, and when you add these two quantities you come out with merely the surface elevation above some fixed datum. I think this point should be made clear.

For example, the author says that "When the jump is produced in a practically horizontal flume, the center of mass of the water is raised as shown by the dotted line in Fig. 8," and a little farther on he says, "The center of mass lowers instead of rises, and no jump is produced."

I think it ought to be made clear there that the center of mass is not the significant thing by itself, but that the position of the water surface above a fixed datum is the significant thing in determining the potential energy.

I also question the expression, "through the turbulent action produced, and probably through much internal impact." To my mind those two things are tied together and are merely two features of the same thing. The turbulent action absorbs and dissipates energy by internal friction and internal impact. So instead of expressing them as two different things, I think they are merely part of the same thing.

One of the points which appealed to me was that the author, as I understand his paper, states that he desired to undertake a rational solution of this problem, but had not fully completed an analysis along purely rational lines, and therefore presents his conclusions as empirical relations, having in mind, I presume, that later he or other workers in this field might tie up these empirical expressions by comparing them with the results derived from a purely rational and mathematical analysis.

I should prefer to have seen a thoroughgoing rational analysis made first before the attempt to derive empirical relations, because after much experience in such problems I have more and more come to the thought that the presentation of results by purely empirical methods is rather dangerous and not conclusive.

For example, in many hydraulic problems we could take the results obtained experimentally and plot them into curves against the particular variables which we believe have the controlling influence, and then derive empirical equations to fit these curves.

Now very often in applying this method you will obtain a series of points, put a smooth curve through them, and then find it is very difficult to say just what the form of equation is that best suits those curves. You might obtain a curve that looks like a parabola, and then apply a parabolic equation. With very little change you might apply a hyperbolic equation or an exponential equation, and usually the accuracy of the experimental data is not sufficient to establish which is the proper contour.

You can often arbitrarily select any number of mathematical equations which give you a curve that will closely fit the one plotted. Therefore for the usual range of experimentation the hydraulic data are not as a rule accurate enough to determine

[6] Consulting Engineer, I. P. Morris Corporation, Philadelphia, Pa. Mem. A.S.M.E.

the form of the curve. We therefore have to assume some form of curve, whether hyperbolic, exponential, or something else, and fit our equations to it, which will give a rough rule that we can apply with reasonable accuracy.

But that does not go to the root of the problem. That is one reason why I think this subject deserves further study by the author and any others whose interest we can enlist in the matter, to investigate analytically the conditions and to determine a really rational solution. It may come out in close agreement with what the author has derived empirically, and again it may not. It may involve other factors.

I should be hopeful that, if such a rational result may be reached, it can be made broad enough to tie the sloping-flume phenomena with the horizontal-flume phenomena so that the single equation will suit either.

I was interested in Mr. Levy's suggestion that friction will require experimental coefficients of correction. But I agree with him that this is a case where much the larger part of the action is that of turbulence and velocity-head conversion, and the friction will play a relatively minor role, so that a purely rational expression should give us quite a close basis for building up our final formula.

I was anxious to obtain the views of R. D. Johnson, of New York, on the subject, because he has been interested in the hydraulic-jump problem, but Mr. Johnson wrote that the time was so short and the subject so complex that he could not present a formal discussion, and could offer only a few suggestions; and I have his permission to read some of these. He writes:

You are of course perfectly right in pointing out an obvious weakness in Mr. Ellms' paper where he tries to deal with the so-called change in the center of mass as an indication of the change in potential energy. As you say, the significant thing is the change in surface elevation.

To make this point a little more clear, it occurs to me that if you take a tank filled with still water and raise the bottom on one side of the tank to a higher elevation than on the other, you can plot in a curve of the center of mass, but that has no significance. The water is not moving, and it does not even represent potential energy, but only the elevation part of it, since the surface elevation is the thing which determines the potential energy, and that is the same throughout the still-water tank.

Also, if you take the flow over a weir, the center of mass curve would run along at the center of the depth in the approach channel and would rise as the water goes over the crest, but there is not any increase of potential energy; in fact, there is a decrease represented by the drop of the surface curve as the water passes over the crest. So this curve of center of area or center of mass is of no significance there. Mr. Johnson continues:

The most serious defect which I find in this paper is the failure to take into account all of the forces which are acting. Take for example the simple case portrayed in Fig. 10; the free forces there acting are a hydrostatic triangle opposed to the flow equal to

$$d_2^2 \div 2$$

(for unit width of flume and unit weight of fluid) and a hydrostatic triangle favoring the flow equal to

$$(Z + d_1)^2 \div 2$$

The difference between these forces should be equal to the rate at which the momentum changes or

$$\frac{Q}{g}(V_2 - V_0)$$

It looks as though this would result in a cubic equation which would have to be solved by trial, but it would not appear to be very much like the author's solution of this particular case.

I, myself, have no disposition to offer any adverse criticism of this paper without putting in enough time to develop a rational formula for his general case of sloping flumes. . . . The author, at any rate, deserves a lot of credit for having tried to adapt an empirical equation to the phenomenon in question, and I have little doubt that his formula is quite accurate for the range already covered by experiments, but I should never be satisfied to make use of such an empirical equation for conditions very much outside of the range of experiments, as this is always a dangerous thing to do, especially in hydraulic problems.

In a second letter, Mr. Johnson says:

I might call your attention to another matter on page 5, next to the last paragraph, under Fig. 9. The condition which he cites would certainly be most interesting if true. As I read it, the author says that the difference between $d_2'$ and $d_1$ is simply that due to the difference in velocity heads between $V_0$ and $V_c$. I can scarcely think I am reading correctly and I should like to know if that is what you read. This would indeed be most remarkable, because there would then be no turbulence whatever if a stream, say, 10 ft. deep at about 18 ft. velocity, should run abruptly into a deep pool over a sharp edge, and furthermore, according to the author, this complete recovery would be independent of the value of $Z$. . . .

If the value of $Z$ is very great so that $V_0$ is substantially zero, then we should have a lifting of the water surface equal to 5 ft., with no turbulence whatever for the case I have cited.

Mr. Johnson further continues in still another letter:

I might call your attention to the author's application of Equation [10] to Fig. 10 on page 6. As I read this equation, it seems to say that the jump according to Fig. 10 is greater than would be the case in a straight flume (that is, with $Z = 0$) by an amount equal to the difference between the velocity heads of that which would obtain after the jump in a straight flume and that which exists due to some value of $d_0$ greater than $d_2$.

It seems quite obvious that the introduction of a vertical drop in the flume bottom equal to $Z$ would reduce the value of $d_2'$ below that of $d_2$ instead of increasing it. His formula is, however, consistent with his statement that the full velocity head would be recovered when $d_1$ corresponded to the critical depth, for then $d_2$ would equal $d_1$ and the rise in surface elevation would be that due to the difference between the velocity heads. This is of course sufficiently wild to require no demonstration of its incorrectness.

Mr. Johnson has plotted a curve (Fig. 12) showing how the results came out graphically. I am merely putting these points

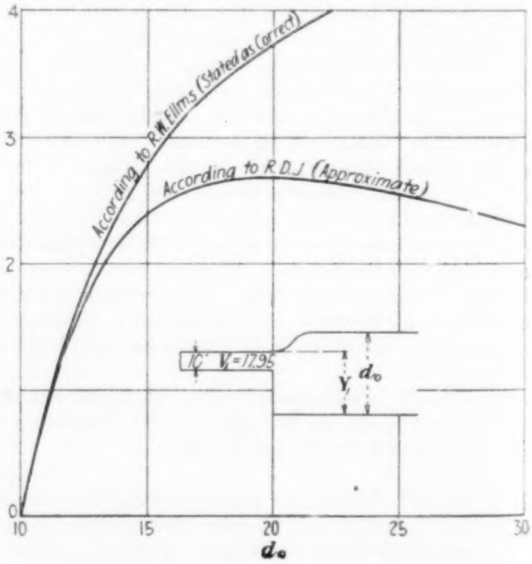

FIG. 12

in at this time, thinking that the author may himself be able to explain the matter. I suspect, however, that these results are merely such as are generally to be expected from an empirical formula based on a relatively narrow range of experimental results when we try to apply the empirical equation to extreme conditions, and that is where they begin to fall down.

I do not want to be understood as submitting these suggestions

in a critical spirit, because, as I said, I have not been able to give the paper enough study to warrant that.

In closing, I want to express my appreciation of the work by the author. I think he deserves much credit for the large amount of experimentation he has put into this and the considerable time he has expended in formulating the results empirically. And he should not be criticized for not having obtained a rational solution. But I am hoping that he may be able to supply further rational analysis of his results in the future. I think that we all ought to encourage just this kind of work on the part of our active engineers, as it is just what the hydraulic art needs, and I say "art" advisedly.

R. L. Daugherty.[7] I have not had time to analyze this paper completely; however, only the first equation is a rational one and all the others are purely empirical without any rational basis whatever. Like Mr. Moody, I should prefer to see a rational analysis made first which would be very general in its scope and would include all dimensions and all cases, and then we should modify that in the light of such experimental data as we should have before us.

I agree also with Mr. Moody that the dotted line showing the path of the center of mass is of very little or no significance. It is the surface curve that really tells the whole story.

I should hope to see more work done in the line of making a rational analysis and then see how that would have to be modified in slight ways in the light of this experience.

I might at this time add something else, which is a side issue. The failure of the St. Francis Dam in California is perhaps one of the most extensive hydraulic experiments of which we are aware.

It seems to me a great pity, so long as the experiment had to come about accidentally, that we could not have taken some real data on it. If it had happened in the daytime instead of at midnight, and if there could have been some observers who could have taken pictures, preferably with a moving-picture camera, or if we could have had some of these gages described in the paper to give us a record of what happened, it would have added enormously to our knowledge of this problem of non-uniform flow, because this paper is a special case of non-uniform flow.

As I see it, this case in California involved two types of non-uniform flow. One is the hydraulic jump that the paper describes, because the depth of the water some distance down the canyon below the dam was greater than the depth of the water immediately below the dam, so there was a hydraulic jump on a large scale. We know that, because the sides of the canyon were previously well covered with brush. Now as you walk down the canyon you see bare, almost polished, rocks to a height of 100 ft. on either side, and we can tell from that what the water surface must have been. So we know that there was a hydraulic jump.

I hope with what we have it will be possible for some careful surveys to be made so that we can perhaps fix the water surface from the evidence we have there. There was a big hydraulic jump below the dam. Then as you go down the stream we have the other phenomenon which is generally known as the "bore," where we have almost a vertical water surface advancing rapidly down the canyon. If we could have had complete data on that, it would be of great value. But I hope that even as it is we may rescue a little information from what happened there from the evidence that has been left behind.

I also wish to thank the author for the work he has done on this subject. It is an important subject, one that has been but very little investigated in reality, and he has added a great deal of real value to our knowledge of it by the careful data he has presented, and it is a very hopeful start in what we trust will be a solution of the problem.

R. L. Sackett.[8] This is a very valuable contribution to the study of hydraulic jump. This phenomenon has become of considerable importance during the last few years, first, as a method of absorbing energy, and now as a means of mixing chemicals preliminary to precipitation in water purification. I think this is a very natural method of approach. Certain data were obtained, and the application of an empirical formula to fit them is quite in line with the usual method of attacking problems of this kind.

The inferences that they have made are sound. We ought to proceed, on the strength of what we have already obtained, to a further analysis by mathematical methods, which should lead us to a final analysis and a solution which would apply to any conditions.

The criticism has been made that the locus of the center of mass was deceptive, or at least of no importance. If we have a given condition such as one depth of flow and a given slope, then of course it is true that the center of mass is not the locus of the center of energy in the consecutive sections. At the same time there is, under a given condition, a very close relation between the locus of the center of mass and the locus of the center of energy and the surface contour. They are all related. If you vary the conditions, you will change the locus of the center of gravity of the section, you will change the locus of the center of energy, and you will change the surface curve, so that while it does not represent anything of great importance, it is related to those factors that are of importance.

We have just built a hydraulic jump at the college, purely for the purpose of absorbing energy, so the erosion below it in an earth canal such as used in irrigation would not be of a character to cut back underneath the concrete and thus endanger it. This subject is therefore of interest to us. Our conditions vary a little, in that the channel below the jump is widened so that it is slightly wider than the channel of approach. The slope of the channel is fixed, but there is an opportunity there to carry on experiments.

### Author's Closure

The author is indebted to the men who have so generously contributed to the discussion of his paper and wishes to express his appreciation for the work they have done, and the helpful attitude they have taken toward the development of a rational solution for this problem.

The empirical equations which the author derived from experimental work satisfied the need for a ready and "exact" method for calculating the tail-water depth of the hydraulic jump when it is produced in sloping and expanding flumes. Formula [10] conforms strictly with present practice in hydraulic engineering. It is substantiated by actual test data which cover a fairly wide range of experimental work. The two slopes tested in the thesis work gave an average deviation of about 6.2 per cent, while a third slope tested by A. G. Levy and J. W. Ellms gave an average of only 2.9 per cent deviation from the corresponding depths as computed by formula [10]. Bidone's original experiments were conducted in a flume which had a slope of about 0.02 ft. per ft. All of his readings were much too great to compare favorably with the depths as computed by the momentum formula. However, if formula [10] is used to correct his results for a sloping flume, a much better agreement between his measured depths and the computed depths will be found.

In the process of developing this empirical formula, the author

[7] Professor of Mechanical and Hydraulic Engineering, California Institute of Technology, Pasadena, Calif. Mem. A.S.M.E.

[8] Dean of Engineering, Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

followed what seemed to him a logical procedure. It is evident that the same reasoning here resorted to cannot be applied when a rational solution is desired. In the discussion and conclusion to the paper, he made an attempt to justify formula [10], and tried to establish some sort of a logical reasoning process which he hoped might finally lead to the true rational solution. He is not surprised that the individual steps should be misleading. Obviously, Fig. 9 is only theoretically possible. As drawn, the friction and sudden expansion losses are great enough to offset almost entirely the gain in head. The curve plotted by Mr. Johnson illustrates this loss in head very clearly. A similar loss in head would be experienced for the condition pictured in Fig. 10.

However, by making the assumptions based on the foregoing theoretical conclusions, the author was able to eliminate the automatic effect of "change of section" experienced with jumps produced in sloping flumes. His deductions were correct, because by making these steps he discovered that by adding the velocity-head term to the depth $d_2$, as calculated by the momentum formula, he obtained formula [10], which contains only one empirical constant and which satisfies all the data far better than formula [3].

It must be remembered that if a flume in which a jump is produced has even a slight slope to it, the discharge of the water above the jump is, theoretically at least, into a body of water of infinite size. A gradual slope of the flume affords excellent diffusing conditions for the water just below the jump, and therefore almost a perfect conversion of velocity head into static head results. Here, friction retards the flow in the usual manner. As the angle of the flume increases, the impact or shock losses increase, and consequently it becomes more and more difficult to regain the velocity head. On this basis a separate "diffusion factor" should be entered into formula [10] which varies with the slope, and which is now an integral part of the constant $c$.

Aside from this action there exists a loss of energy which is inherent in the process of producing the jump in a sloping flume. This loss is due to the change of direction of velocity after impact, and, so far, the author has not been able to account for it by a rational analysis. The constant $c$ in formula [9] at present takes care of this condition in an empirical way. A study of the rise and fall of the center of mass of the water may aid in a rational solution of the problem. The author made use of it only because he thought it might furnish some clew to the solution of this phenomenon. All methods that he has tried for a rational solution failed to give anything but indeterminate results.

The author is in hope that subsequent discussions will clear the matter up, for he firmly believes that the empirical solution will eventually yield to a rational one.

# Notes on "A New Method of Separating the Hydraulic Losses in a Centrifugal Pump"[1]

By MICHAEL D. AISENSTEIN,[2] BERKELEY, CALIF.

THE author has received queries as to how to proceed when $\left[Q, \frac{h - h_0}{Q - Q_0}\right]$ does not plot as a straight line for the entire range of $Q$, which is a very common occurrence. This can be best illustrated by an example.

Given the characteristics of an 8-in. two-stage pump, operating at 960 r.p.m., the inlet diameter of the impeller $d_1 = 9$ in., the outlet diameter $d_2 = 21$ in.

First tabulate the values of $Q$ and the corresponding values of $h$, as shown in Table 3.

The points $\left[Q, \frac{h - h_0}{Q - Q_0}\right]$ when plotted do not lie on a continuous straight line but form two straight lines $AB$ and $BC$, Fig. 4$a$. Since the analysis is based on the consideration of the point of the maximum efficiency, the points lying on the $AB$ portion should be included only. Following the procedure indicated in the paper, we have

$$3a + 4800b = -0.1851$$

$$2a + 5200b = -0.1737$$

Solving for $a$ and $b$,

$$a = -0.02146$$

$$b = -0.00002515$$

Substituting these values in the equation

$$\frac{h - h_0}{Q - Q_0} = a + b\,Q$$

and solving,

$$h = 237.8 + 0.05902\,Q - 0.00002515\,Q^2$$

Further, $u_2 = 88$ ft. per sec. and $u_1 = 37.7$ ft. per sec. From Equation [16] of the paper, $A = 196.6$ per stage, or 393.2 for two stages.

From Equation [22],

$$D = \sqrt{393.2 - 237.8} = 12.48$$

The point of maximum efficiency occurs at 2200 gal. per min., therefore

$$E = \frac{2200 \times 0.00002515}{12.48} = 0.00443$$

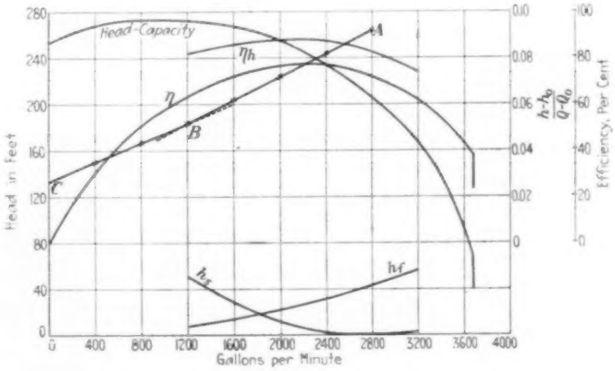

Fig. 4$a$ Characteristics of 8-In. Two-Stage Pump Used in Example

From Equation [24]

$$c = 0.00000553$$

From Equation [23]

$$B = -0.05148$$

**Substituting all these values in Equation [15],**

$$h = (393.2 - 0.05148\,Q) - \underset{\text{(Friction loss)}}{0.00000553\,Q^2} - \underset{\text{(Shock loss)}}{(12.48 - 0.00443\,Q)^2}$$

The friction and shock losses are now to be entered in Table 3.

It is evident that in this case the losses are determined for the region covered by the $AB$ line only. This being the region of the maximum efficiency, gives the desired information to the designer.

# Friction in Dredge Pipes

By JAMES H. POLHEMUS,[1] PORTLAND, OREG., and JOHN R. DuPRIEST,[2] MINNEAPOLIS, MINN.

*This paper presents some information on pipe friction for dredge pipe 29 in. inside diameter and with velocities up to about 20 ft. per sec. The data were obtained during some recent tests of large hydraulic dredge pumps, and on account of the large size of the pipe and the high velocities encountered it was thought worth while to present the information for the benefit of others engaged in dredge work.*

*An analysis is also given of the data showing how the equation for loss of head in pipe lines can be modified so as to give a constant friction factor as velocity varies instead of having both velocity and friction factor vary in the equation.*

THE subject of pipe-line friction is always an interesting one to those engineers engaged in any way with the handling of liquids, and a great many experiments have been made under different conditions with different fluids and with various kinds and sizes of pipe to determine the loss owing to so-called pipe friction.

Some time ago the writers made very thorough tests of several large dredge pumps to gather data for use in designing the main pump for the Port of Portland's new Diesel-electric dredge *Clackamas*. The pump on this new dredge was to have a greater operating range than any dredge pump of its class previously built, and for this reason it was very desirable to obtain the best information possible before getting out the designs.

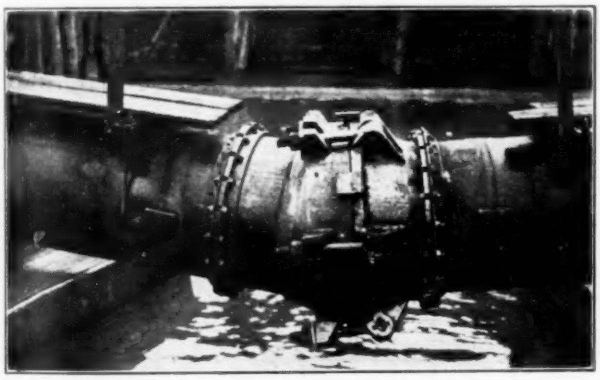

FIG. 1 FLEXIBLE RUBBER SLEEVE CONNECTOR

During these pump tests the opportunity was presented to obtain other valuable information pertaining to the operation of pipe-line dredges, and this paper presents some information based on data gathered at that time.

It is not often that thorough tests can be conducted on pipes as large as 29 in. inside diameter and with velocities as high as 20 ft. per sec., and for this reason it is hoped that the results obtained from these tests will add something to the literature on the subject of pipe-line friction. The pipe used in these tests was butt-welded steel pipe $^1/_2$ in. thick made up in 30-ft. lengths with flanges riveted on it. The pipe was bolted up in 90-ft. sections, and rubber sleeve connectors about 3 ft. long were used between the 90-ft. sections. Fig. 1 shows a picture of one of the flexible rubber connectors.

The length of pipe line between gages used for determining pipe friction was 1046 ft. and included 11 rubber sleeve connectors. The pipe had been in use for only a short time, was highly polished, and was probably as smooth as it is possible to get dredge pipes. The rubber sleeves were practically new and in first-class condition. The pipe line can therefore be considered as in the best condition throughout.

Fig. 2 shows a diagrammatic arrangement of the set-up for the tests, and it will be noted that on the end of the floating line a number of nozzles were attached. By varying the size of the nozzles, together with changes in speed of the pump, any conditions of pressure and velocity could be obtained within the capacity of the pump. Data were taken during three different

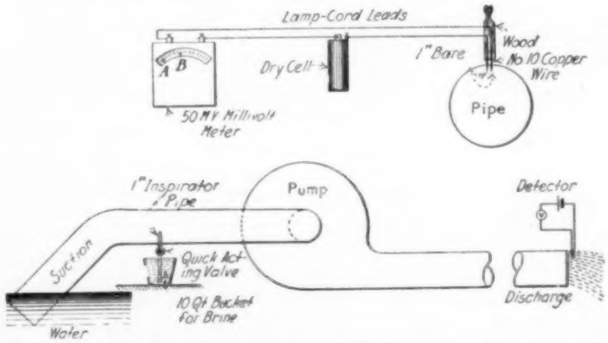

FIG. 2a SCHEME OF ELECTRICAL METHOD FOR VELOCITY MEASUREMENTS

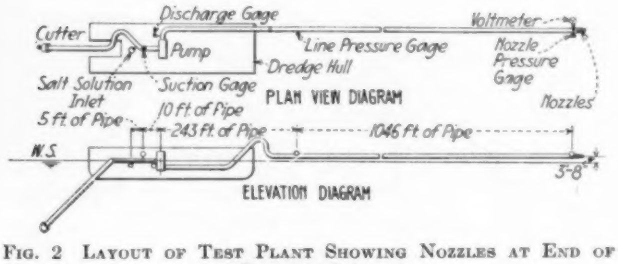

FIG. 2 LAYOUT OF TEST PLANT SHOWING NOZZLES AT END OF FLOATING LINE

pump tests, and it is believed that sufficient information is available to leave little doubt as to the accuracy of the results obtained.

## MEASURING PIPE-LINE VELOCITY

The value of the results presented in this paper depends on the accurate determination of the velocity of flow through the pipe, and a few words of explanation here will show how the velocity was obtained.

The method used to determine the velocity of flow through the pipe line is known by dredge testing engineers as the salt-solution method and is carried out as follows: Two insulated electrodes (Fig. 2a) are inserted in the pipe line, separated by a few inches. A dry cell and millivoltmeter are connected between the electrodes. The resistance of the circuit is such that, with ordinary river water flowing, a small deflection is shown on the voltmeter,

[1] General Manager and Chief Engineer, Port of Portland. Mem. A.S.M.E.

[2] Professor of Mechanical Engineering, University of Minnesota. Mem. A.S.M.E.

Contributed by the St. Paul Local Committee and presented at the Summer Meeting, St. Paul-Minneapolis, Minn., August 27 to 30, 1928, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

but when a salt solution is introduced into the stream and passes the electrodes, the deflection of the voltmeter increases considerably owing to the better conductivity of the salt water. The sensitiveness of the method will be appreciated when it is known that the resistance of ordinary river water will vary from about 2000 to 5000 ohms per cc., whereas the resistance of a 5 per cent solution of pure salt water will be about 15 ohms per cc.

During these tests about 2 gal. of saturated salt water was introduced into the pipe line at each velocity test. Two velocity determinations were made for each run, and when the two did not agree closely, a third test was usually made.

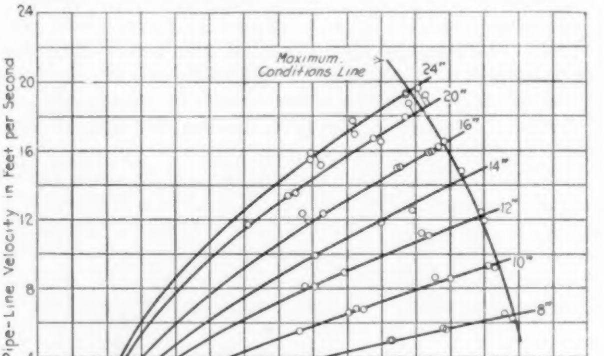

Fig. 3 Curves T1–6

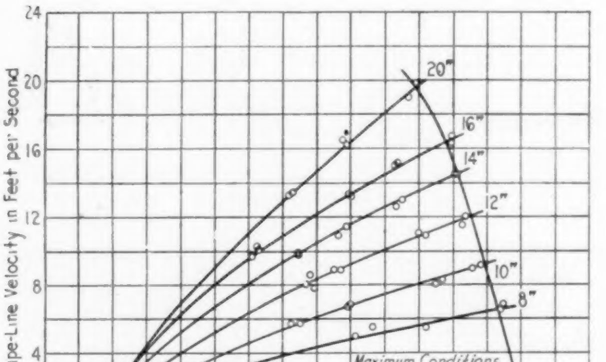

Fig. 4 Curves T2–6

The following readings were taken during the tests: Time required for the salt solution to enter the pipe; time required for the salt solution to pass the electrodes; time from the opening of the valve to admit the salt solution until the salt water reached the electrodes, i.e., when the voltmeter needle first began to change. The velocity was then found from the following equation

$$\text{Average velocity} = \frac{1}{2}\left(\frac{D}{T} + \frac{D}{T + Y - X}\right)$$

where $D$ = distance in feet between point where salt water was introduced and the location of electrodes

$X$ = number of seconds to introduce salt water

$Y$ = number of seconds for salt solution to pass voltmeter

$T$ = number of seconds from time of opening salt-water valve until solution reached electrodes.

The velocities as found by this method are plotted in Figs. 3, 4, and 5, and the results obtained give good curves. On account of having families of curves it is very much easier to detect errors and also much easier to give proper locations to the curves. A careful analysis of the results by cross-checking with other curves showing different data for the same tests indicated that, for the points which do not fall on the curves, speeds are in error in some cases and velocities are in error in others. Altogether the data for the three tests are very consistent, and certainly very little change could be made in the locations of the various curves.

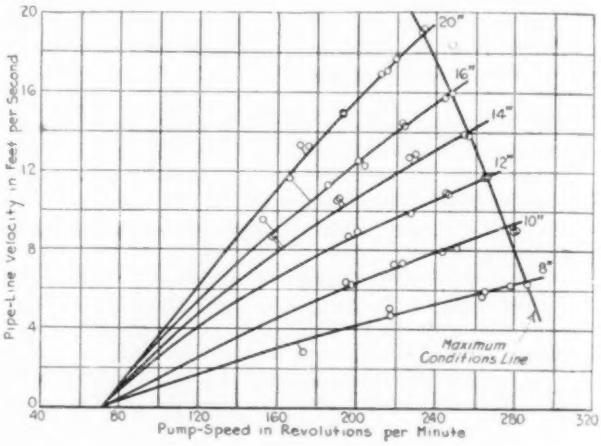

Fig. 5 Curves T3–6

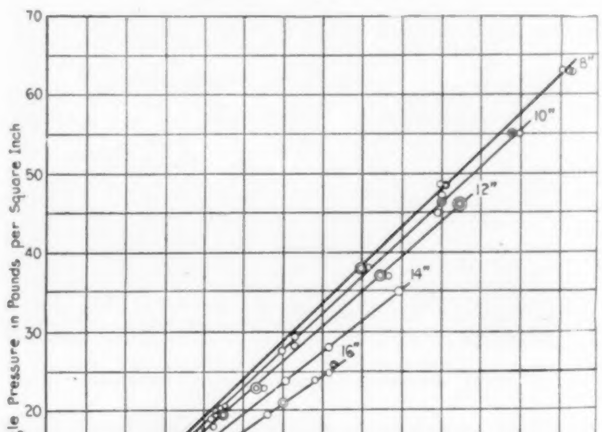

Fig. 6 Curves T1–7

### Head Lost in Line

The difference between the line pressure, which was taken about 40 ft. behind the dredge, and the pressure just ahead of the test nozzle should represent the head lost in the 1046 ft. of floating line. In the first efforts to study this data the values as observed were subtracted to give head lost in the line, but it was soon found that slight errors of observations caused a large percentage of error when dealing with the small heads lost at

low velocities. To reduce the effect of observation errors curves were plotted, as shown in Figs. 6, 7, and 8, using line pressure as abscissas and nozzle pressure as ordinates.

It will be noted that the curves are essentially straight lines, except for the large nozzles, and as the scales chosen place the curves near the 45-deg. position there is little chance for error

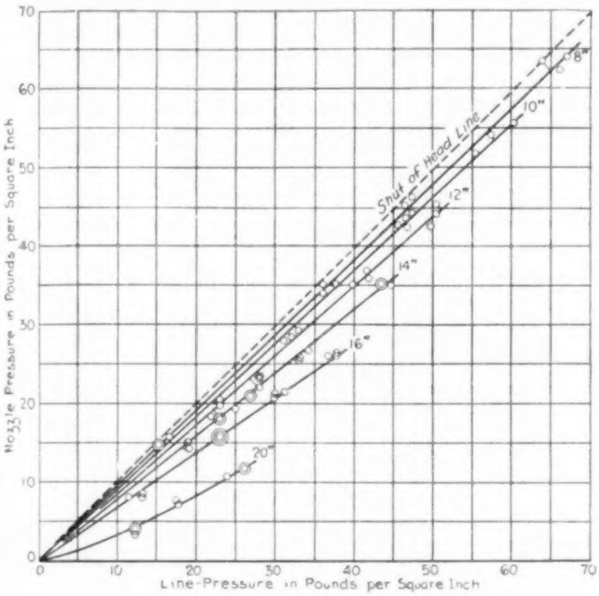

Fig. 7 Curves T2–7

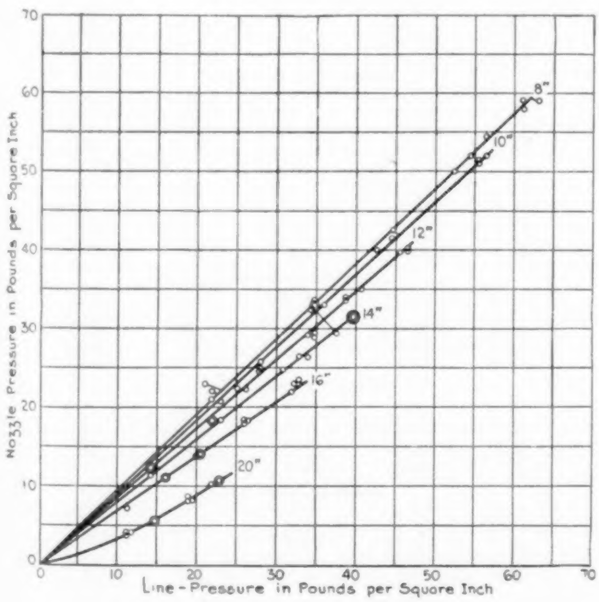

Fig. 8 Curves T3–7

in the location of these curves. The results obtained by use of these curves confirm this as they are remarkably consistent. The friction factors were first found by use of the well-known equation

$$H = \frac{flv^2}{2gd}$$

where $H$ = head lost in line in feet of water
$l$ = length of line in feet

* Lost heads are for 1046 ft. of dredge pipe 29 in. inside diameter.

$v$ = velocity of water in feet per second
$d$ = diameter of pipe in feet
$g$ = 32.2
$f$ = friction factor.

Data for finding $f$ are given in Tables 1, 2, and 3, and were found in the following way: For given selected line pressures at the first gage, pressures at the second gage or nozzle pressures were read from curves T1–7, T2–7, and T3–7, Figs. 6, 7, and 8. For the same line pressures, pump speeds were read from curves T1–17, T2–17, and T3–17, Figs. 9, 10, and 11. For the pump speeds obtained, pipe-line velocities were then read from curves T1–6, T2–6, and T3–6, Figs. 3, 4, and 5. With these data as given in Tables 1, 2, and 3, values were calculated for the friction factor $f$. The results were very consistent and agreed very well with some published data that were available.

Curve T2–25, Fig. 12, shows the relation between the friction factor $f$

$$f = \frac{2gd \times H}{l \times v^2}$$

and pipe-line velocity as found in this way for one test, and the other tests gave similar curves with values just as consistent. The writers, however, feel that there should be little cause for change in the friction factor as velocity changes in a very smooth pipe, and also, since the variable value of $f$ is more troublesome to use in practice, it was thought worth while to study the data carefully to see if a better relation could not be obtained.

The results were analyzed by the use of logarithmic paper, and it was found that if an exponent of about 1.75 were used for $v$ instead of the second power, the coefficient $f$ became a constant. It has long been thought by some engineers that the second power was not correct, and a value of 1.75 has been suggested by several writers.

In Fig. 13 all of the data for lost head against pipe-line velocity

* Lost heads are for 1046 ft. of dredge pipe 29 in. inside diameter.

are plotted for the three tests. The large circles are plotted from the equation

$$H = \frac{flv^n}{2gd}$$

where $n$ = 1.75, and
$f$ = 0.0280

and the small circles are test-data points. Considering the large scales used in plotting these data, the test points fall remarkably close to the mathematical curve.

There are about one-hundred points from test, plotted in Fig. 13, covering three tests made on different days and each test lasting between 12 and 18 hours. The points grouped around any given velocity, say 12 ft. per sec., represent conditions for several different speeds and pressures at the pump.

In view of the large amount of data available, the length of time of the tests requiring changing observers every eight hours or less as the dredge crew changed, the results are very consistent, and it is believed that they will be found to be entirely trustworthy.

While the results from these tests give a friction factor of 0.028 for 29-in. dredge pipe in good condition, it must be remembered

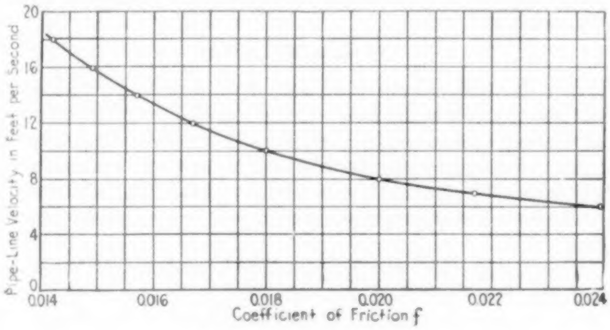

Fig. 12 Curves T2-25

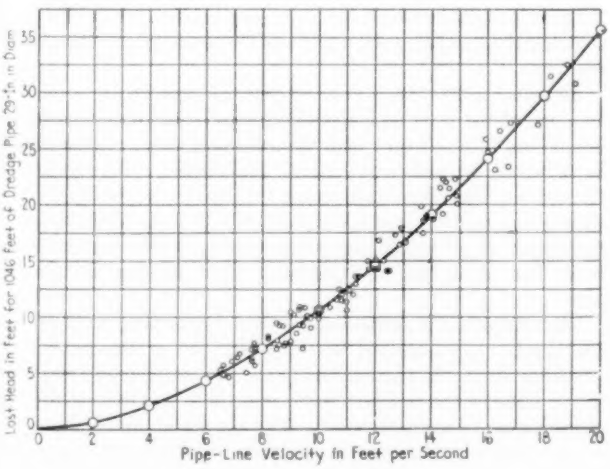

Fig. 13 Curves CC-14B

that the rubber sleeve connections between the 90-ft. sections of pipe cause some loss owing to disturbance to flow, and therefore smooth steel pipe with flush joints of uniform diameter should give a slightly lower coefficient.

The shore pipe uses metal slip joints, and while each joint probably offers much less resistance to flow than a rubber sleeve, the joints come every 30 ft., and the total resistance in any long line will probably agree very closely with the results obtained by use of the equation given.

### Conclusions

While the old method of using a variable friction factor depending on the velocity, as shown in Fig. 12, will give good results, the constant friction factor seems more logical. The values for $f$ and also for $n$, as found from these tests, are for pipe 29 in. inside diameter and may not hold for other sizes of pipe, as the head lost may not vary as $\frac{1}{d}$.

It is hoped that in the near future tests can be conducted on other sizes of dredge pipe and compared with the results given in this paper, to find out if the head lost owing to friction is inversely proportional to the diameter or whether the equation should take the form

$$H = \frac{flv^n}{2gd^x}$$

If it is found that $d$ should have an exponent slightly different from 1, the values for $f$ and $n$ as found in the foregoing, may change slightly. However, it is believed that suitable values

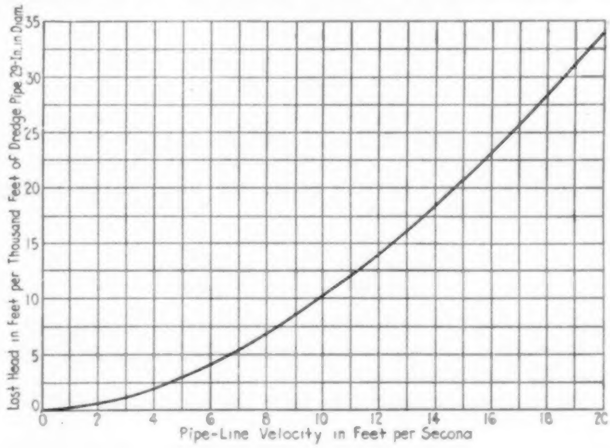

Fig. 14 Curves CC-14C

can be found for both $n$ and $x$ which will give a constant value for $f$ for all sizes of dredge pipe.

It is hoped that engineers who have accurate test data available will make comparisons with this work to check the accuracy of the results as given, and the authors will be very glad to discuss the subject further with any engineers interested in this problem.

## Discussion

Michael D. Aisenstein.[3] It is interesting to compare the results obtained by the authors with the results predicted from the equations of flow embodying the Reynolds criterion. This may be accomplished as follows:

The exponential formula, in general, derived by means of the principle of dynamic similarity, is

$$h_f = Kl \frac{v^n}{d^{3-n}\ \nu^{n-2}} \qquad [1]$$

or

$$h_f = \frac{l}{d}\frac{v^2}{2g}\,\phi\left(\frac{vd}{\nu}\right) \qquad [2]$$

where $v$ = velocity of flow in feet per sec.
$l$ = pipe length in feet
$h$ = head in feet
$\nu$ = kinematic viscosity in English units, and
$g$ = gravitational constant = 32.2.

For steamline flow, that is, when $vd/\nu < 2000$, the coefficient of friction

$$\phi\left(\frac{vd}{\nu}\right) = \frac{64}{\frac{vd}{\nu}} \qquad [3]$$

[3] Hydraulic Engineer, Byron Jackson Pump Mfg. Co., Berkeley, Calif. Jun. A.S.M.E.

For turbulent flow, or when $vd/\nu > 2000$, the writer, from available experimental data of different authorities, determined the coefficient to be:[4]

$$\phi\left(\frac{vd}{\nu}\right) = \frac{0.167}{\left(\frac{vd}{\nu}\right)^{0.170}} \qquad [4]$$

Substituting in [2],

$$h_f = 0.167\, \nu^{0.170} \frac{l}{d^{1.170}} \frac{v^{1.830}}{2g} \qquad [5]$$

or for clean water having a kinematic viscosity of 0.00001077 at 68 deg. fahr.,

$$h_f = 0.0239 \frac{l}{d^{1.170}} \frac{v^{1.830}}{2g} \qquad [6]$$

Inspecting Equations [1], [5], and [6], one can see that the exponents for $d$ and $v$ are mutually related, and have actually a physical meaning. For this reason the writer suggests using formula [5] or [6] instead of

$$h = \frac{flv^n}{2gd^x} \quad \text{or} \quad h = \frac{flv^n}{2gd}$$

with exponent 1.75, as both these formulas are rather arbitrary.

Moreover it can be seen that formula [5] is more general as the viscosity term is included.

The authors overlooked to state the temperature and kind of water they pumped, and the writer assumes that clean water at temperature of about 60 deg. fahr. was used.

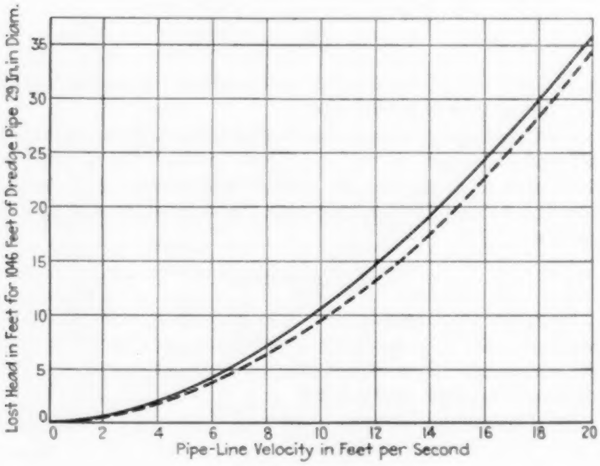

Fig. 15

Full line replotted from Fig. 13. Broken line calculated by means of formula $h_f = 0.0239 \frac{l}{d^{1.170}} \frac{v^{1.830}}{2g}$

Having substituted the different values of velocities in Equation [6] for the same pipe which was used by the authors, the writer obtained a $v$–$h_f$ curve (Fig. 15).

It may be noticed that this curve agrees close enough for engineering purposes with the curve plotted in Fig. 13.

The writer would like to see tests made to obtain the pipe-friction loss for dredged mixtures of different densities, to see if it is possible to predict by means of the Reynolds criterion the pipe friction when the percentage of spoil to be pumped and the screen analysis and density of spoil are known.

[4] Trans. A.S.M.E., vol. 50, no. 3, Jan.-Apr., 1928, paper no. HYD-50-2, p. 6.

O. M. Leland.[5] Would the angles made by the various sections of the pipe either on the shore or on the floating section make very much difference in the friction losses? In the case of a dredge moving around, the pipe line is not moved any more than is necessary, and in the floating section one frequently finds considerable angles in the pipe. On the shore line there are more sections and likely some angles possibly worth considering. I wonder if the authors found any difficulties or variations on account of those angles and whether they reduced the angles to a minimum in all cases.

M. W. Davidson.[6] Was any effort made by the men who made this test to introduce electrodes at different points across the current?

## Authors' Closure

Replying to Mr. Leland, no tests were made to determine the loss due to bends in the line. The line used during the tests was all floating, with no bends. Occasionally the waves from passing boats would cause some disturbance, but this was not serious at any time. The floating line as used in practically all of the work on the river has one right-angle bend only, placed at the donkey scow.

The floating line extending to shore is anchored at the scow, and the line extending from the dredge to the scow swings as the dredge advances and is also lengthened as the dredge advances.

The shore line is made up of 30-ft. lengths, with slip joints, and the line is flexible enough for long, easy bends; Y's are used for splitting the line for making fills and for changing the location of the line.

Replying to Mr. Davidson, no attempt was made to make a traverse of the pipe with the electrodes. This was considered, but it was believed that with the velocities obtained the turbulence would be sufficient to give practically uniform velocity throughout the pipe, considering the length of the line. The electrodes extended into the pipe from 1 to 2 in. This is about the length used when in regular operation, as long electrodes are easily bent or broken by stones and sticks passing through the line.

Mr. Aisenstein's discussion is very interesting and is appreciated. As mentioned in the early part of the paper, the checking up on the friction loss in the dredge pipe line was only a side issue of the real test work, and there was no intention of doing accurate research work. The results obtained, however, were better than had been anticipated, and it was for this reason they were offered, believing they might be of interest to some few engineers.

The authors are well pleased to find that the results agree so closely with Mr. Aisenstein's theoretical equations. The equation proposed in the paper for loss of head was put intentionally in as simple form as possible so as to be used by practical dredge men and its shortcomings were recognized.

Clear water at about 60 deg. was pumped at all times during the tests. No serious effort was made to determine pipe-line friction when pumping material, as it is almost impossible to maintain even approximately constant conditions of flow for any great length of time unless the material being pumped is consistent throughout the swing of the dredge, and even then the line conditions are constantly changing, depending on the skill of the lever man.

# Flow of Water Over a V-Notch

By JOSEPH TARRANT,[1] SOUTH HARROW, MIDDLESEX, ENGLAND

*In this paper the author presents a formula for finding the flow of water over V-notches with angles ranging from 90 deg. down to 27 deg., which is based on the experimental results given in D. Robert Yarnall's paper on the "Accuracy of the V-Notch-Weir Method of Measurement," presented before the A.S.M.E. in December, 1926. He compares this formula with others which have been proposed, checks it with data obtained by several investigators, and concludes that, within the range of angles specified, it will prove useful. An alignment chart based on the formula is given, from which discharges may easily be read off.*

HAVING occasion recently to look up data on the flow of water over a V-notch, the author read the account of a series of experiments on the flow over notches of various angles carried out by Mr. D. Robert Yarnall, Mem. A.S.M.E., and described by him in a paper[2] which was reprinted in MECHANICAL ENGINEERING of January, 1927.

The experiments were carried out on notches of 90 deg., 53 deg. 8 min., 27 deg., and 13 deg. 8 min., for the purpose of verifying the value of the coefficient $C$ in the formula

$$Q = CH^{5/2}$$

where $Q$ = discharge in cubic feet per minute, and
$H$ = head over weir in inches,

and the tables and curves given in the paper show that the value of $C$ varies according to the head, for each of the four notches tested, and appears to reach a stable value in each case at a head of about 15 in.; in the case of the 90-deg. notch, $C$ varied from 0.303085 at 4.988 in. head to 0.29775 when the head reached 15.0522 in.

In the discussion which followed the paper, Mr. M. P. O'Brien[3] gave, for each notch, a formula with a fixed index, these formulas being as follows:

| Angle | Formula |
|---|---|
| 90° | $Q = 2.48\ H^{2.49}$ |
| 53°8′ | $Q = 1.242\ H^{2.48}$ |
| 27° | $Q = 0.613\ H^{2.475}$ |
| 13°8′ | $Q = 0.3312\ H^{2.42}$ |

$Q$ being in cubic feet per second, and $H$ in feet.

It occurred to the author that such a range of tests as those carried out by Mr. Yarnall might be used for finding a formula which could be used for notches of all angles between the largest and smallest notches, and to this end the experimental results were plotted logarithmically. It was found difficult to obtain a formula of simple type which would cover the whole range from 90 deg. down to 13 deg. 8 min., but the formula

$$Q = 2.415 \tan\left(\frac{\theta + 1.5°}{2}\right) H^{2.485}$$

where $Q$ = cubic feet per second
$H$ = head in feet, and
$\theta$ = angle of the notch in degrees,

gives results which agree very closely with the experimental results on the 90-deg., 53-deg. 8-min., and 27-deg. notches, and may be presumed to hold for all angles between 90 deg. and 27 deg.

In Table 1 discharges calculated by the formula are compared with Yarnall's experimental results.

TABLE 1 DISCHARGE CALCULATED BY THE PROPOSED FORMULA $Q = 2.415 \tan\left(\frac{\theta + 1.5°}{2}\right) H^{2.485}$ COMPARED WITH YARNALL'S EXPERIMENTAL RESULTS

While few published records exist of discharges over notches having angles less than 90 deg. (though formulas have been suggested for these smaller angles, as mentioned later), experiments by Thomson,[4] Barr,[5] and Gaskell[6] on 90-deg. notches afford experimental results by which the proposed new formula may be tested. The comparison of the experimental and calculated discharges is given in Table 2.

TABLE 2 DISCHARGE CALCULATED BY THE FORMULA $Q = 2.415 \tan\left(\frac{\theta + 1.5°}{2}\right) H^{2.485}$ COMPARED WITH TESTS ON 90-DEG. NOTCH BY THOMSON, BARR, AND GASKELL

After making extensive tests on sharp-edged notches of angles of 120, 90, 60, 30 deg., and 28 deg. 4 min., V. M. Cone[7] obtained the following formulas:

[1] Assoc-Mem., Institution of Mechanical Engineers.
[2] Trans. A.S.M.E., vol. 48 (1926), p. 939.
[3] Ibid., p. 956.
[4] *Civil Engineer and Architects' Journal*, Nov., 1858, Dec., 1861, and April, 1863.
[5] *Engineering*, April 8 and 15, 1910.
[6] *Proc. Inst. C. E.*, vol. 197 (1913–14), p. 258.
[7] *Journal of Agricultural Research*, vol. 5, no. 23, March 6, 1916. (U. S. Dept. of Agriculture.)

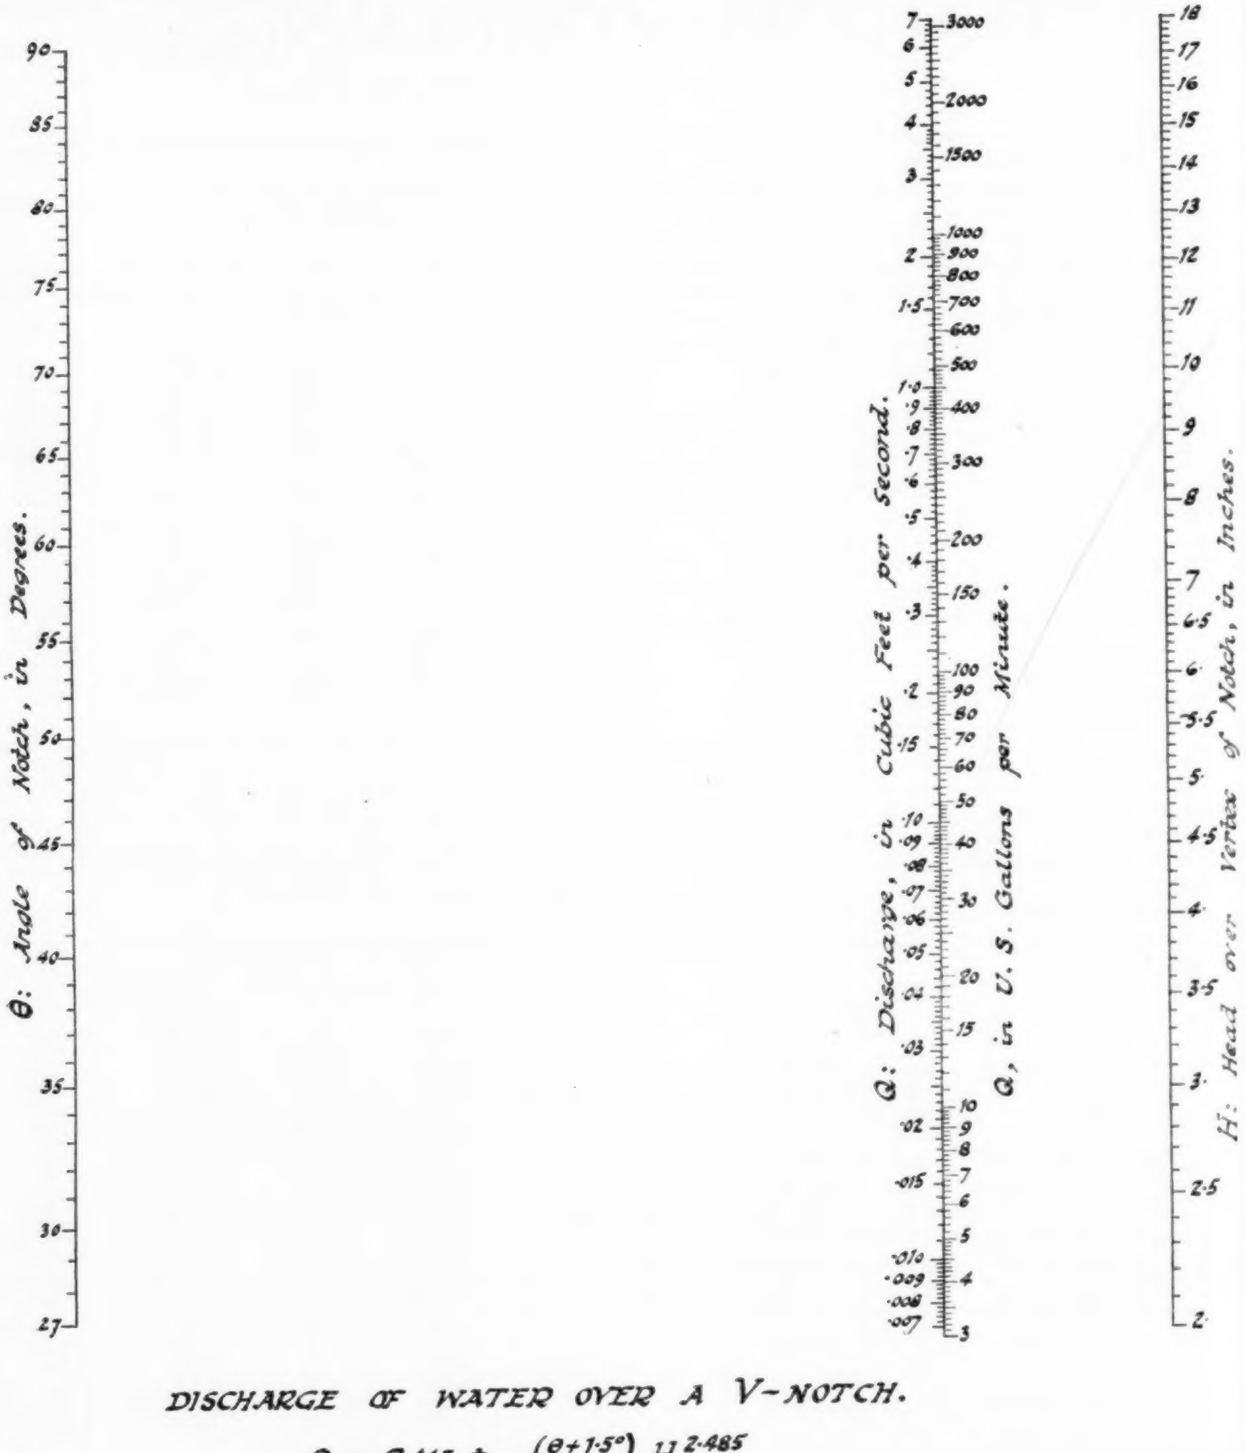

Fig. 1 Alignment Chart for Discharge Over V-Notches

| Angle | Formula |
|---|---|
| 120° | $Q = 4.400\ H^{2.4870}$ |
| 90° | $Q = 2.487\ H^{2.4805}$ |
| 60° | $Q = 1.446\ H^{2.4705}$ |
| 30° | $Q = 0.6848\ H^{2.4476}$ |
| 28°4′ | $Q = 0.6405\ H^{2.4448}$ |

and gives the following general formula for all these notches up to and including 90 deg.

$$Q = (0.025 + 2.462\ S)H^{\left(2.5 - \frac{0.0195}{S^{0.75}}\right)}$$

where $Q$ = cubic feet per second
$S$ = slope of sides, expressed decimally, and
$H$ = head in feet.

Cone found that notches of 120 deg. were impracticable for general use, as the nappe adhered to the edge for about $^1/_{12}$ ft. at the upper portion, although the notch was only $^1/_{32}$ in. thick. (Rowell[8] also mentions this, and recommends, instead of a wide-angle notch, several 90-deg. notches spaced so that there is no interference of flow. For non-interference he recommends that the notches be spaced apart a distance equal to seven times the maximum head.)

A comparison of the author's proposed general formula with Cone's 90-deg. formula is seen in Table 2.

Arranged for certain angles, the proposed formula becomes:

| Angle | Formula |
|---|---|
| 90° | $Q = 2.48\ H^{2.485}$ |
| 75° | $Q = 1.904\ H^{2.485}$ |
| 60° | $Q = 1.437\ H^{2.485}$ |
| 45° | $Q = 1.037\ H^{2.485}$ |
| 30° | $Q = 0.681\ H^{2.485}$ |

and a comparison of these formulas for 60 deg. and 30 deg. with the Cone formulas for the same angles is found in Table 3.

TABLE 3 COMPARISON OF FORMULAS FOR ANGLES OF 60 DEG. AND 30 DEG.

| | Head in feet | $Q$ (proposed formula) | $Q$ (Cone formula) |
|---|---|---|---|
| 60° | 1.25 | 2.502 | 2.51 |
| | 1.0 | 1.436 | 1.446 |
| | 0.75 | 0.706 | 0.714 |
| | 0.50 | 0.2567 | 0.261 |
| | 0.25 | 0.0458 | 0.04706 |
| 30° | 1.25 | 1.186 | 1.182 |
| | 1.0 | 0.681 | 0.6848 |
| | 0.75 | 0.3349 | 0.3401 |
| | 0.5 | 0.1217 | 0.1255 |
| | 0.25 | 0.02172 | 0.0230 |

Gourley and Crimp[9] give the formula, $Q = 2.48\ nH^{2.47}$, where $n$ is the tangent of half the angle of the notch. It will be found that the proposed formula gives results which, for the smaller angles, agree somewhat more closely with the observations than does this formula.

Barnes's[10] formulas,

$Q = 2.48\ H^{2.48}$ for 90 deg., and
$Q = 1.244\ H^{2.48}$ for 54 deg.

give results which are in close agreement with those obtained by the proposed formula when applied to these angles.

The experiments on which the formula is based were carried out on a sharp-edged notch, beveled off to $^1/_{32}$ in. in thickness, the upstream edge being square, in a tank so proportioned that the velocity of approach was negligible.

In a paper summarizing the work on the V-notch, it may not be out of place to state the general conditions necessary for satisfactorily measuring the flow by this method.

The edge should be of metal, $^1/_{16}$ in. thick, and square on the upstream edge; the plate should be set in a vertical plane and have its upstream face quite smooth.

(Barr found that coating the upstream face of the weir with coarse emery increased the discharge 2.4 per cent at 3 in. head, over that of a weir with a plain surface.)

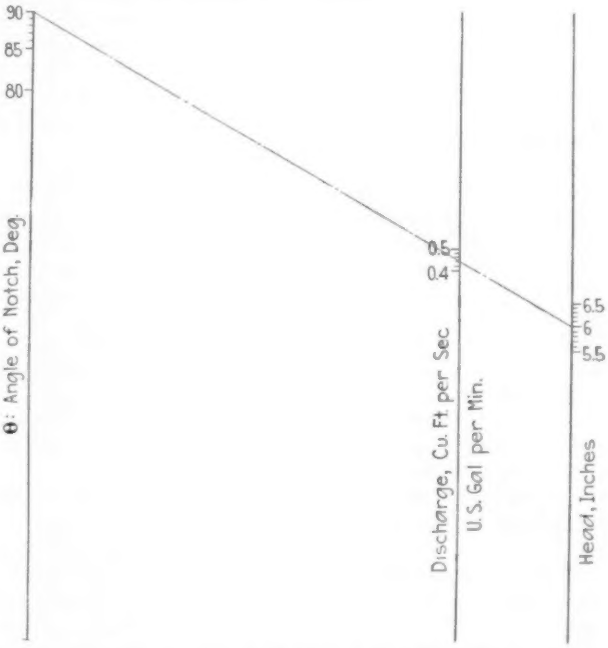

FIG. 2 SHOWING CONNECTOR LINE TO BE USED WITH CHART OF FIG. 1, AND GIVING AN EXAMPLE OF ITS USE

The width of channel should be such that the velocity of the water approaching the notch is not greater than 0.5 ft. per sec. The water should be stilled by means of suitable baffles. The width of the channel should be eight times the head for non-interference with the flow. (Reducing the width of the channel has the effect of increasing the flow by reducing the contraction at the sides of the notch.) The channel floor on the upstream side should be below the vertex a distance equal to three or four times the head. (Barr.)

Cone recommends measuring the head at a point at least either $4H$ upstream of weir or $2H$ to the side of the end of the crest.

Downstream, the level of the water should not rise above the vertex.

Where the velocity of approach exceeds 0.5 ft. per sec., Barnes suggests a correction for the head by adding to the observed head an amount equal to 0.01 $u$, where $u$ is the mean velocity of the water in the approach channel in feet per second.

Further tests on notches of small angles are desired for checking purposes, but it is believed that the proposed formula will prove useful within the range of angles specified. An alignment chart from which discharges may readily be read off in cubic feet per second or U. S. gallons per minute is given in Fig. 1, and an example of its use in Fig. 2.

# Progress in the Iron and Steel Industry

## Contributed by the Iron and Steel Division

Executive Committee: F. C. Biggert, Jr., W. W. Macon, C. S. Robinson, Geo. T. Snyder

THE year 1927 was one of unusual achievements in the American iron and steel industry, among which two have attracted particular attention. The first was the manufacture of large seamless tubing the foundation for which was laid in the preceding year. It was during the current year, however, that the success of the undertaking was proved. The reasons for undertaking it are well known. With an increase in the depth of wells, complaints as to the strength of pipe then used came from the oil country, with an insistent demand for large-size, heavy-walled seamless tubing.

### Manufacture of Large Seamless Tubing

Three companies have so far replied to this demand. One of these installed a German pilger mill, another provided both the German pilger and an American automatic mill, while a third limited its equipment to an American mill only. In all of these cases there was at first considerable doubt as to the ability to pierce billets of the size required for these machines. It was found ultimately that not only was there no trouble in regard to piercing, but that even rolled billets proved to be unnecessary and round ingots could be used as the raw material for the tubes. There are still certain mechanical problems requiring attention, but the success of the large seamless-tube mill in America has been decidedly established. As a matter of fact, greater production has been obtained in America from German mills than has ever been obtained in Germany.

### Continuous Sheet Rolling

The other development which has attracted special attention is continuous steel-sheet rolling. This does not belong entirely to the current year, as the installations at Ashland, Ky., and at Butler, Pa., were substantially completed late in 1926. Such was the promise of these applications of continuous rolling of sheets, however, that several other mills of the same character have since been laid down, and some of them have been put into operation. Among these may be mentioned the mills of the Laclede Steel Co. at Alton, Ill., the Weirton Steel Co. at Weirton, W. Va., the Trumbull Steel Co. at Warren, Ohio, and the American Sheet & Tin Plate Co. at Gary, Ind.

The introduction of continuous sheet rolling has been accompanied by further development of the four-high mill and the use of roller bearings in the big rolls, thus further familiarizing the steel industry with anti-friction bearings in their larger aspects.

These two developments among others served to direct increased attention toward research among tonnage steel makers. To mention only the more prominent units, the Bethlehem Steel Co. had already segregated research and development work into a special department in 1926. This year the United States Steel Corporation organized a research department and has given it an unusually high standing by making it report directly to the Finance Committee, which is the highest governing body of the corporation. George Gordon Crawford, president of the Tennessee Coal, Iron & Railroad Co., and Prof. John Johnston, of Yale University, have been placed in actual management of the new organization, while to the committee deciding on the program of research have been attracted men of such prominence as Frank B. Jewett, vice-president of the American Telephone & Telegraph Co., and Professor Millikan of the Norman Bridge Laboratory, University of California.

Throughout the year the steel industry has been permeated with a certain feeling of unrest and search for economies. The amount of business done by the mills has been of almost record capacity, but prices obtained for the products have been comparatively low, and the general feeling has been that profits were not commensurate with the unusual volume of business. It has been felt, therefore, that the greatest attention to costs must continue without relaxation, to insure profitable operation in coming years.

### Mill Drives

Steam as a means for driving the larger mills continued to lose ground. Among the outstanding electrifications of blooming-mill drive may be mentioned the installation of a 4000-hp. reversing motor at the plant of the Donner Steel Co. in Buffalo. A similar installation has been made by the Bourne-Fuller Co. at its Upson plant, while the Colorado Fuel & Iron Co. has put through an unusually ambitious project of electrification. In all these cases it is claimed that a better product is obtained at a lower cost. In the case of the Bourne-Fuller installation with the engine drive a maximum mill speed of 175 r.p.m. was obtained, and a speed of only 140 r.p.m. with a motor drive. It is not expected that as large maximum production will be obtainable from the electrified mill as before, but this is not considered important in view of mill and market factors modifying demands on the mill.

The progress made by powdered-fuel firing in central stations is making its way into the steel-mill field as well. At the Pueblo Works of the Colorado Fuel & Iron Co., powdered coal is used in the power plant. At the Central Iron & Steel Co. in Harrisburg, Pa., however, it is used in the heating furnaces of the plate mills. At first a unit pulverizer was installed, but later it was discarded and a central pulverizing plant is now used.

### Rolling Mills

The size and capacity of modern mills are well illustrated by performance at the works of the Lukens Steel Co., Coatesville, Pa., where steel ingots weighing 63,000 lb. each have been converted into slabs on the 206-in. plate mill. This is believed to be a record for size of ingots rolled. According to *The Iron Age* for May 12, 1927, the ingot was rolled into a slab 130 in. wide, 200 in. long, and $8^3/_4$ in. thick. Each of these slabs is used to make a "flywheel" blank $8^3/_4$ in. thick and 121 in. in diameter, the blank being cut from the slab by means of a portable automatic oxyacetylene cutting machine. The blanks are to be used in making herringbone-gear speed-reduction units.

A new structural mill at the Homestead Works of the Carnegie Steel Co. has been completed. It includes a blooming mill of 54-in. size, claimed to be the largest blooming mill in existence. Another feature is that it is to roll the new wide-flange Carnegie beams. Only two operators will control the main or auxiliary drives of this blooming mill. One man using a single master switch is capable of setting the three screwdowns on the roughing and intermediary mills. They automatically stop at predetermined settings by means of a specially designed limit switch, and secure the proper speed relations between the motors driving the main and edging stands for any condition of draft. This man controls several other operations, thirteen in all, during the rolling of each beam, a fact which is a good illustration of

the complexity of the apparatus used and the resulting amazing simplicity and extent of control in operation.

In the past year the so-called Neuves-Maisons process for the heat treatment of steel rails has become known. This consists of an intermittent quenching of the head of the rail in a definite quantity of cold water, this quantity depending on the weight of the rail. It is claimed that this treatment increases the tensile strength and also extends the hardening effect beyond the depth of normal wear.

### The Foundry Field

In the foundry field one of the interesting developments has been the application of hot blast to the cupola (H. K. Viall, *The Iron Age*, Oct. 20, 1927). In this case a standard cupola is used with only an upper wind box added below the charging floor. Carbon monoxide is drawn from the gases of combustion and used to preheat the air. Two years of operation have shown that combustion in the hot-blast cupola is more complete than in the cold-blast. Certain economies due to this more perfect combustion appear to have been established.

Further effort is being made in foundries to simplify and cheapen production, this being a more vital matter for foundrymen than ever before as castings today are in competition with forgings, stampings, automatic-machine products, and, finally, welded parts. In some directions castings have already lost out to welding. The latter has successfully replaced castings, for example, in large generators, parts of machine tools, etc. The foundry is meeting this situation in two ways. One is by permanent-mold casting, which has been applied, for example, to the making of Holley carburetors; the other is the employment of conveying devices. An interesting example of this latter class is the continuous unit for the manufacture of small gray-iron castings installed at the Elmira Foundry Co., Elmira, N. Y. (*The Iron Age*, Aug. 18, 1927.)

This report is only a general survey of the most important developments of the year, and no attempt has been made to cover progress in detail. This has been made necessary by the fact that the new Division is only just completing its organization.

# Developments in 4-High Rolling Mills

## The Rolling of Wide and Thin Material; Early Mills and Experimental Designs; Technical Features of the Mills; Capacity and Power Consumption

By F. C. BIGGERT, JR.,[1] PITTSBURGH, PA.

UNTIL somewhat over a year ago progress in the rolling of strip steel had practically come to a standstill. The existing mills had succeeded in hot-rolling strip up to about 24 in. wide by 12 gage, and narrower widths as thin as 16 or 28 gage. Some material may have been made thinner than 12 gage in widths approaching 24 in., but I believe that the widths and thicknesses stated above represent the best commercial accomplishments of the time.

If wider material was to be rolled, it was evident that fundamental changes in mill construction must be made since increasing roll diameters, with the inevitable increase in neck friction which they imply, had about reached the practical limit.

The use of roller bearings was naturally considered, but no bearing could be designed which would support the required load and be small enough to assemble in the 2-high mills then in use.

We had built the 206-in. plate mill at Lukens Steel Company, and in it we used the 4-high mill, not so much to reduce power consumption as to limit the size of the chilled working rolls to dimensions within the facilities of chilled-roll makers. This mill had been successful and had demonstrated the possibilities of the 4-high type as a means of producing wide and relatively thin material of exceptionally accurate gage. That is to say, this plate mill had been found capable of rolling plates as thin as $^3/_8$-in. in widths up to 16 ft. and having a uniformity of gage from edge to center quite as good as had previously been produced in ordinary widths. The life and behavior of the rolls were remarkably good. No spalling occurred, and the medium-carbon-steel backing rolls maintained their shape well.

Some difficulty with fire-cracking of the chilled rolls occurred due to the very large ingots used and the slow and heavy drafts in the early passes, but it was evident that with slabs such as would be used in strip mills, this would not be serious.

### Difficulty in Rolling Wide and Thin Material

Considering the possibilities of wider strips in the light of this plate-mill experience, we concluded that the same type of mill offered the means required. There were difficulties, however.

In rolling thin material, the power cost becomes a matter of importance, and while the 4-high mill is inherently more efficient than the older types, yet, if run on ordinary bearings, the power per ton would still be rather high.

A large and expensive installation rolling thin material must deliver at high speed if tonnage, commensurate with the installation cost, is to be obtained, and with ordinary bearings, this would involve excessive heating.

On thin material a mill must maintain its setting much more accurately than in ordinary rolling. The wear of ordinary bearings, which, in thick rolling, is of small importance, becomes vitally important when the thickness approaches $^1/_{16}$ in.

All these difficulties could be overcome if roller bearings could be obtained capable of sustaining the loads involved.

### Early 4-High Mills

Our engineers had developed the requirements thus far and had made some inquiries indicating that suitable bearings could be obtained, when we were called to the plant of Rome Brass & Copper Company, Rome, N. Y., to advise with that company as to means of improving their practice in producing sheet copper.

Having studied copper-rolling practice, with which we had previously been entirely unfamiliar, we concluded that the 4-high roller-bearing mill met the requirements completely.

The question of roller-bearing design was discussed with Mr. W. Messinger of Philadelphia, and having determined sizes which, upon rather meager data, appeared to meet the requirements, a mill was built. It has proved satisfactory.

This mill had scarcely started and was still in a highly experimental state when Columbia Steel Company came into the market for a steel strip mill to roll 30-in. wide material down to 12 gage; afterward changed to 36 in. wide by 12 gage.

Here was a chance to try out the 4-high principle in a big way, but we were poorly prepared, having still only imperfect data on which to base designs. We decided to make a clean breast of the matter and see if Columbia would go along with us in a large-scale experiment. The allurements were great and we convinced them that the experiment was worth making. They installed a universal roughing mill followed by four stands of 4-high hot mills arranged in tandem and five stands of similar cold mills. The E. W. Bliss Company supplied the cold mills.

Generally speaking, these mills have been successful, although bearing troubles have been encountered, to some extent, on the hot mills. This is primarily due to rolling 14- to 16-gage material, in which case the steel is too cool when it is delivered to the finishing train. A universal mill is not fast enough for a strip-mill rougher where the gage to be finished is thinner than 12. Sheets as wide as 36 in. and down to 16 gage are being produced on the mill, but changes will be required before this can be done satisfactorily. As the mill now stands, 14 gage by 36 in. wide is its commercial limit.

Before the Columbia mill design was well started, Weirton Steel Company decided to install a tandem train of 9 hot mills and two 5-stand trains of cold mills to roll 48 in. wide. The experiment was getting too hot for us and we insisted that reliable data be obtained before proceeding with designs.

Pressure-measuring devices and also devices for measuring neck friction in ordinary strip mills were deviced, built, and applied, and from these devices we obtained remarkably consistent data upon which to base both bearing loads and motor powers.

The Weirton hot mills have now been in operation for some three months, and so far neither bearing nor roll troubles have appeared. Widths up to 38-in. have been hot-rolled to 16 gage commercially, and 36 in. wide 17 gage has been produced experimentally.

Other steel companies have also taken up this new type of mill. Lukens Steel Company has an 84-in. plate mill built among the first. Trumbull Steel Company has remodeled its 16-in. wide mill using five stands of 4-high in its finishing train and have thus increased its capacity from 18-in. to 30-in. widths. A

[1] President, United Engineering and Foundry Co., Pittsburgh, Pa. Mem. A.S.M.E.

Presented at a meeting of the Iron and Steel Division, Youngstown, Ohio, Nov. 10, 1927, of The American Society of Mechanical Engineers.

further change in the roughing train will permit rolling 36 in. Youngstown Sheet & Tube Company has a single stand with 72-in. roll. American Sheet & Tin Plate Company is installing six stands which will be referred to later, and there are numerous others. Some 80 stands of 4-high roller-bearing mills, hot and cold, have been contracted for within a period of less than two years, indicating the remarkable interest aroused by the development.

### Hot and Cold Rolling

Just what will be the outcome of this development is difficult to say. There are the two distinct fields of hot and cold rolling to which the mill is eminently suited. In hot rolling, it is safe to say that 16 gage is near the practical limit, although American Sheet & Tin Plate Company proposes to go to 18 gage by 28 in. wide, and will doubtless accomplish this.

Leaving the hot mill at 16 or 18 gage, we have the choice of further reduction through cold strip mills or by packs on ordinary sheet or tin mills.

Both of these methods probably have their field of usefulness. For very light gages, particularly tin plate, it may be that the hot pack will prove most economical. This is the method being tried out by American Sheet & Tin Plate Company, and it will surely reduce the cost as compared with present-day practice.

Down to 24 or 26 gage, particularly for full-finished and similar bright stock, there seems to be little doubt that the cold-strip process is best. The operation of these cold mills is just beginning. At present we do not know either the minimum thickness or the maximum speed which may be commercially obtained, and until these factors are determined, it will be impossible to decide which process will survive.

Another factor of importance is the question of coating. We are not yet sure that the cold-rolled material will take a satisfactory coat of either tin or spelter, but the probability is that by suitable preparatory processing such coatings may be applied.

Where feasible, the cold-strip process seems to have great advantages. Labor is much reduced; crop losses are almost negligible; pickle cost is from one-half to one-fourth of that for the pack process; frequently it will be advantageous to have the finished material in strip form rather than in sheets, and the remarkable accuracy of gage should increase the demand for strips.

On the whole, we are disposed to believe that reduction by the cold process will ultimately prove to be the economical method of producing the large-tonnage gages, perhaps including tin plate.

The accuracy of rolling with these mills is quite remarkable. It is not difficult to hot-roll strips 259 ft. long 30 in. wide and $^1/_{16}$ in. thick with edge-to-center and end-to-end variations within 0.003 in. At Weirton this degree of accuracy has been exceeded in regular production. I have personally callipered coils 36 in. wide by 0.080 in. thick which showed only 0.002-in. edge-to-center variation. But this practice has been abandoned and about 0.004-in. fullness is being allowed on account of the difficulty of handling the more accurate coils in the cold mills. There is much less difficulty in cold rolling if the metal has an appreciable fullness at the center.

The practice in the hot mills is to start with a 3-in. thick slab regardless of the finished gage, and, with suitable edging equipment, an excellent edge is produced on the finished strip. The edges are somewhat rounded but very straight and smooth, so that even for the most exacting sheet requirements it will only be necessary to side-trim about $^1/_8$-in. The length of strip is so great (200 to 400 ft. hot-rolled and 300 to 1200 ft. after cold rolling) that end crop loss becomes almost entirely negligible.

### Capacity

A hot mill arranged like that at Weirton can easily produce 40 long tons per hour of 30-in. wide 16-gage material. The theoretical discharge of this material at the usual finishing speed of 800 ft. per min. is 135 long tons per hour, so that placing the average production at 40 tons is doubtless conservative.

The possibilities of the cold mills are not so well established, but it is fairly well proved that a delivery speed of 200 ft. per min. can be maintained and that a reduction of 60 per cent in thickness can be obtained in a 4-stand train.

If, then, we start with 16 gage 30 in. wide, we may reduce to about 24 gage which, for 30-in. wide material delivering at only 150 ft. per min., amounts to a theoretical discharge of 10 tons per hour. Cold mills can be run on a very high production factor on account of the great length of entering piece, so it seems very safe to say that such a train should produce 8 tons per hour of this material. This rate of production has been exceeded for short periods, and seems a very conservative estimate, especially when we remember that there is good probability of attaining speeds higher than that assumed.

### Power Consumption

Power consumed per ton of product has not yet been well established, because all the mills now in operation are running intermittently and under adverse operating conditions, but such data as are available indicate a power requirement about one-half that used in ordinary strip mills for corresponding sizes. On 16-gage material reduced from 3-in. slabs, we believe 80 kw-hr. per ton is a safe figure for hot rolling. Reducing 60 per cent cold from hot-rolled material of 12 to 16 gage, will require about 30 kw-hr. per ton.

The ordinary production of sheet mills is one short ton per hour per mill. On 24-gage sheets, we may allow one long ton per hour as a monthly average per mill.

On this basis and that of the figures previously quoted for hot and cold strip mills, we may assume that one hot-strip mill, such as those at Weirton or Trumbull, with enough cold mills to reduce its product from 16 gage to 24 gage, will be equivalent to 40 sheet mills.

But the sheet mills require sheet bar as their raw material, whereas the strip mill requires slabs which come direct from the blooming mill.

To make a true comparison, we must, therefore, place one hot strip mill with its complement of cold mills against 40 sheet mills and a very good sheet bar mill. The two plants will cost about equal amounts and should produce equal tonnages.

### Tin-Plate Mills

The problem of producing tin-plate and sheets of corresponding thickness by the new methods is particularly interesting, and the American Sheet & Tin Plate Company is to be congratulated upon the steps it has taken in this direction.

Their scheme is to reduce to about 18 gage in a 4-high strip mill, and match, double, and finish on their existing tin-plate mills. The entire roughing operation is thus transferred to the high-production strip mill; the scrap loss should be reduced because of the very accurate dimensions of the pack at the doubling point, and finishing mills may be run at a higher rate because of the reduced roll heating.

Incidentally, this company has burned no bridges since its hot strip mill will be equally well adapted to roughing for cold mills, should it be later found economical to finish cold.

So much for the historical and economic side of the development. From an engineering standpoint, the following may be of interest:

### Use of Roller Bearings

We have used roller bearings of the parallel-roller type on

the backing rolls, because we believed that this type was most suitable to the extreme loads to be carried. We do not know that this is true, but it is to be remembered that in starting this development, we were working in the dark. Speed, load, and available space for assembly considered, these bearings carry several times the load of any roller bearing previously used. Not only is the duty required greater than has been previously demanded of bearings of equal dimensions, but also the manufacture of such sizes had been, by no means, standardized. On this account, we doubted the applicability of formulas of all roller-bearing manufacturers, and were forced to rely largely upon our own analysis in determining both sizes and type of bearings.

The results of practice so far have been fairly satisfactory. On cold mills we have had no trouble, as the loads may be calculated with fair accuracy. Some of the earlier hot mills have given trouble which has been traced to two important sources: first, the excessive loads due to the rolling cold steel, and second, the unavoidable stresses due to cobbles, broken rolls, and similar accidents.

The increase in rolling pressure due to cold steel may easily double the load on the bearings. For instance, at Weirton, measurements taken at the beginning of a run when the first few slabs were not well heated, as compared with corresponding measurements a few minutes later, showed pressures in the ratio of 4 to $2^1/_2$, and the cold slabs were only about 100 to 200 deg. fahr. low in temperature.

There is no means for measuring the momentary pressures due to accidents, but it is obvious that they will increase the demands upon the bearings.

Neither of these occurrences causes immediate failure of bearings, but their repetition may ultimately result in failure, and good safety factors, combined with good heating and good mill practice, are necessary to obtain good bearing performance.

Working-roll bearings used so far have been of ordinary mill-type bronze. The loads on these bearings are theoretically very small, and when the rolls are properly aligned, they are practically quite small. Since specially good alignment is necessary if good rolling is expected, regardless of bearings, and since the rolls, once properly aligned, have little tendency to change their position, there is little need of more refined equipment.

Roller bearings have been suggested for the working rolls, but the small advantage, difficulty of assembly, cost, and almost certainty of destruction every time a roll breaks, have prevented our recommending them.

### Size of Rolls

Sizes of working rolls have been determined from the size of coupling necessary to transmit the required torque. We have based our designs upon elaborate full-size tests to destruction.

Backing rolls have been made of sufficient diameter to accommodate the required bearings, as this usually gives a roll of ample stiffness.

An interesting development in regard to working-roll diameter is that it has no appreciable effect upon the power consumption of the mills. This is, of course, contrary to all previous conceptions, but tests over a wide range of diameters have shown that for like reductions, the power per ton is almost exactly constant.

Of course, the rolling pressure increases with increasing roll diameter, and with ordinary bronze bearings, the larger necks absorb more power. This is the reason that in ordinary mills, the power per ton increases with increasing roll diameters. The friction coefficient of roller bearings is in the order of 0.0009, and consequently the power absorbed by necks is so small that it has almost no effect upon the total power consumption.

This is important since it removes the principal argument for minimum-diameter working roll, and permits the use of rolls large enough to stand severe accidental stresses.

### Motion of Rolls

Another prevalent idea that has been disproved is that the rolls of a mill tend to move out of the housings in the direction of the movement of the material.

The fact is that with equal diameters of top and bottom working roll, there is no tendency to move with the piece, but a back pull toward the entering side just sufficient to pull the material into the mill.

If the material is carried on roller tables moving at the same speed as the mill, this pull is zero and in no case can it be more than the friction due to the weight of the material.

This may be demonstrated by putting exactly equal rolls in any 2-high or 4-high mill and examining the lost motion of the chucks. They will be found usually to bear against the housing post on the entering side and may be displaced by a very slight pressure applied between chuck and housing.

This is not true when the rolls are of unequal diameter nor in the case of a 3-high plate mill where the middle roll is friction-driven from top or bottom rolls.

In the 4-high mills, it has been found advantageous to set the working rolls a small distance off center from the backing rolls. Usually this has been toward the delivery side, although they seem to work about equally well if offset toward the entry side.

We do not know any good reason for this displacement unless it be that it definitely establishes the direction in which the rolls will settle when the piece enters. If they are exactly on center, small unavoidable differences in diameter or other inaccuracies, may cause one end to settle backward and the other forward, whereas by giving a definite offset, they must settle uniformly. Whatever the reason, mill operators find it convenient to offset the rolls as much as $^1/_4$ in. and obtain more uniform results by so doing.

### Composition of Rolls

In the hot mills, after experimenting with rolls of various composition, it appears that fairly high-carbon alloy-steel backing rolls and chilled alloy-iron working rolls will give the best results, although ordinary mild-chill working rolls have given good service where it has been possible to finish at proper temperature.

The cold mills have worked well with medium-carbon-steel backing rolls and hardened-steel working rolls. Ordinary chilled backing rolls have also given good service, and on cold mills it appears that any reasonably hard roll will serve for the backing rolls.

On both hot and cold mills, the experience available is not sufficient to warrant a definite statement as to the best combinations of working and backing rolls, but it is evident that rolls can be made which will give commercially acceptable service.

## Discussion

Lloyd Jones.[2] The application of mills with backed-up rolls is not new, and has been practiced throughout the metal-rolling industry continuously in various forms and shapes for over 60 years. There are approximately five types of backed-up mills, of which the 3-high is in most general use, with the 4-roll and the cluster types following in the order named.

For the rolling of sheets and strips, the 4-roll type and the cluster type are better adapted than 3-roll type, and will eventually supersede it altogether. As to the relative merits of the two

[2] E. W. Bliss and Co., Salem, Ohio.

outstanding types of backed-up mills, namely the 4-roll and cluster types, their merits may be presented as follows:

*Four-Roll Type*

1 Shorter distance from the edge of the housing to the center of the mill

2 Smaller number of rolls.

*Cluster Type*

1 No bearings for holding the work rolls in alignment are necessary

2 The working roll cannot wear out of alignment, hence the cluster-mill operator does not experience the difficulty which the 4-roll operator experiences, due to the terrific end thrust of the working rolls when they become slightly crossed

3 The working rolls can be more quickly changed, as there are no bearings to handle

4 The working rolls automatically align themselves when placed in the mill by coming in contact with the two supporting rolls, eliminating the human element in lining up the mill

5 The contact pressure between the work rolls and the supporting rolls is approximately 30 per cent less per inch of face on the cluster mill, as compared to the 4-roll mill

6 The working roll is supported in both directions of force, and hence small diameter rolls can be used to accomplish the same work

7 With equal diameter of working roll, and with the ratio of backing-up roll to the working roll approximately 2 to 1, which is the general ratio, the cluster mill has approximately 40 per cent greater capacity.

There have been difficulties in holding the rolls in alignment on the 4-roll type. The brasses on the necks become worn, or the mill is not set in correct alignment, and the rolls quickly develop an end thrust which makes the changing of the roll-neck brasses necessary at frequent intervals. To overcome this tendency, the last 4-roll mill shipped to the American Sheet and Tin Plate Company was equipped with roller bearings on the working rolls as well as on the supporting rolls. This was possible because the mill was to be used for cold-rolling purposes, and the working rolls were made of hardened tool steel, which allowed a reduction of the neck diameter sufficient to install the bearings, and at the same time gave sufficient strength to prevent the neck from twisting off.

It is a question in our minds whether this can be successfully done when the mill is used for hot-rolling purposes, especially with rolls made of chilled iron. In this case we have to deal with a metal of low strength, and the torsional stresses would probably twist off the neck.

Another illustration having to do with supporting the rolls in both directions is found in the following experience: If a cobble takes place on the 4-roll mill, the working rolls are apt to break and fly out of the mill. On the cluster type of mill, there was an accident in which metal being rolled escaped the stripper, and passed around the working roll between the supporting rolls approximately six times before the mill was stopped. The only damage that occurred was that the working roll was marked and had to be taken out and redressed. No damage was done to the supporting rolls or to the roller bearings, and the six thicknesses of metal were reduced to the single thickness being rolled, the six laminations being actually welded together cold. This was a remarkable example of the enormous pressure which roller bearings will stand.

As regards the application of roller bearings to mills, this, like the backed-up-roll principle, is old as to the writer's knowledge, roller bearings on both 2-high mills and backed-up mills have been in actual use for probably 16 years in this country.

We have been applying roller bearings for the last three years on all types of mills, 4-high, cluster type, and also on the ordinary 2-high mills. Our experience so far with roller bearings has been excellent, as we have had no failures or replacements to date.

The construction of the 4-roll and cluster types of mills lend themselves ideally to the application of roller bearings. This is one of the reasons why mills of these types are rapidly coming into favor. The power saved by the use of the small diameter rolls is not as great as the power saved by the use of roller bearings. The roller-bearing application, however, is spreading to 2-high mills, and we have a number of them in operation at the present time.

With reference to the adjustment of rolls in the backed-up mills, there is no difference in the principles involved, and the only departure has been the application of electric power to the screw-downs in place of hand power. This, of course, is not new on plate mills, blooming mills, etc., but is new to the sheet and strip industry. In regard to the adjustment of the rolls as far as alignment is concerned, our practice is to build the mill so that the workman has nothing whatever to do with it.

In the cluster mill the working rolls align themselves. In our 4-roll mill for cold rolling we put roller bearings on work rolls and take away all adjustment features. For hot rolling, where we have difficulty applying roller bearings to the working rolls, we believe that the best solution to this problem will be the adoption of the cluster type of mill in place of the 4-roll mill. This will also solve several other difficulties present in the 4-roll mill which has up-to-date been generally used for hot rolling, namely (1) the alignment of the working rolls, (2) increasing the life of the supporting roll surface by from 30 to 50 per cent, (3) decreasing roller-bearing troubles now experienced, and (4) reducing work-roll breakage.

Another interesting feature about backed-up mills is that on account of the small arc of contact with the metal being rolled, the total bending load on the mill is considerably less. This cuts down the deflection or spring in the mill, and in many cases obviates the necessity for crowning the rolls. The practice of shaping the surface of the roll to deliver a sheet or strip within commercial tolerances has been common practice ever since the speaker has had anything to do with the steel business. When the first cluster mill was installed at Huntington in the early part of 1923, we assumed that it would be necessary to crown the working rolls and started that mill with the one roll straight and the other one crowned. The backing-up rolls were all straight cylinders. We soon found that we did not need as much crowning, and this has been gradually reduced.

This question of shaping the rolls is becoming of less importance every day, and our practice now is to ship the mills from our shops with rolls ground perfectly straight. Whether crowning of the rolls is necessary or not seems to depend a good deal upon the product which is rolled in the mill. With the use of roller bearings, which eliminates the heat produced by neck friction, the swelling of the rolls at their ends due to increased temperature is being eliminated, and this in turn also has a tendency to do away with the old practice of shaping the rolls.

It might be well at this time to touch slightly upon the historical phase. About 1913 there were eight cluster mills in operation, and one 4-roll mill. About 1916 the second 4-high mill was installed at Lukens Steel Company. From then there is a gap of approximately seven years, until 1923, and since then there has been a tremendous building of backed-up mills.

What caused this sudden revival of the backed-up mill?

During 1922, the Internationl Nickel Company, at its plant at Huntington, West Virginia, was making full-finished nickel and monel-metal sheets. In order to secure the desired surface it was

found necessary to grind, polish, and buff the sheet before sending it out to the trade. This was a slow and costly process.

In talking the matter over with their Dr. Thompson and Mr. Wotherspoon, the writer proposed cold rolling as a solution. We conducted some experiments and found that by reducing the thickness by cold working, we could secure a surface which would eliminate the grinding process. These experiments were conducted on the ordinary 2-high mill with strips approximately 18 in. wide.

To accomplish the same amount of reduction on sheets 36 in. on the ordinary 2-high cold-rolling sheet mill, of which there were several in the plant, the rolls being 26 in. in diameter, we found it would be necessary to make from 40 to 60 passes. The writer then proposed a mill of the backed-up principle, and we were all convinced that that was our only solution to the problem.

When it came to the choice of backed-up mill, there were two types. The writer was well acquainted with the 4-roll type built for Lukens Steel Company as all drawings for this mill, prior to being issued to the shops, had his signature of approval on them. He was also familiar with the cluster type of mill which had been operating since 1913. In studying over the advantages of the two types of mills at that time, his preference fell to the cluster type, and this type was installed at Huntington.

We quickly found that we could accomplish in 3 to 4 passes on this mill what took 40 or more passes on the regular 26-in. mill. This mill was visited by practically every sheet and strip manufacturer in the country, and many of the prominent sheet manufacturers sent sheets to Huntington to be cold-rolled.

This was really the starting of the modern strip method of rolling sheets, because it removed the limitations on the old hot- and cold-rolling strip practice, and allowed the adoption of this practice to widths wider than had been rolled, and further encroached upon the sheet trade.

Charles L. Huston.[3] When the World War broke out in 1914, and the United States in process of time was called upon for war supplies of all kinds, the demand for heavy steel plates for Scotch-marine boilers, and for wide and heavy plates for the modern type of locomotive became acute, plate mills were so busy with plates of ordinary size that they did not wish to risk breaking down their mills with this heavy work.

To meet this situation, the Lukens Iron and Steel Company (now Lukens Steel Company) decided to build a mill large enough to take care of all present and prospective demands. The customary 3-high plate mill was found to be inadequate because of the difficulty and risk involved in making and using the long chilled rolls of large diameter which would be required.

After a careful study of the field, an adaptation of the 4-high mill built by Julian Kennedy for the Carnegie Steel Company, about 1890, was given consideration.

This mill had been intended for rolling armor plate, but, for some reason, was found to be not quite satisfactory for this purpose, and was turned into a slabbing mill. It was built with working rolls of comparatively small diameter, these being driven directly from the reversing engines, through the pinions.

The possible explanation of the reported difficulties seemed to be that the large supporting roll, underneath the lower operating roll, would fail to reverse promptly when the driving engines reversed, because the weight of the lower operating roll, added to the weight of the large supporting roll and all resting upon the journals of the supporting or backing-up roll, resulted in an extra frictional resistance upon the journals of the supporting roll, which, added to the inertia of the heavy supporting roll when the motion of the mill was reversed, caused slippage between the working and supporting rolls and possibly wore little grooves or irregularities in the surface of the supporting roll, and these through irregular support of the working roll made objectionable marks on the surface of a finely finished rolled plate.

[3] Vice-President, Lukens Steel Co., Coatesville, Pa. Mem. A.S. M.E.

The simplest way of remedying this trouble seemed to be to provide a direct drive for the bottom or supporting roll, which, geared to the lower pinion, would, through a suitable friction device, be of sufficient power promptly to reverse the bottom supporting roll, and yet avoid conflict of speeds and possible breakage of the driving mechanism when the rolls, after some period of wear, might become changed in their relative diameters and therefore be of a ratio different from that of the pinions at the driving end.

The contract for building this mill on a cost-plus-percentage basis was given to the United Engineering and Foundry Company, Mr. F. C. Biggert, Jr., now President, being at that time Vice-President and Chief Engineer. Mr. Biggert, with his engineering staff, took special care in working out the designs and proportion, of this mill, which, being heavier than anything heretofore attempted, as it had to take care of very heavy as well as wide work, had to be of a new design throughout. Mr. Lloyd Jones, then with the United Engineering and Foundry Company, was given charge of working out the details of the mill in cooperation with the writer and the engineering staffs of the Lukens Steel Company and the United Engineering and Foundry Company.

The drive for the mill consisted of 46 by 70 in. diameter, 60 in. stroke, twin, tandem-compound, condensing, reversing engines geared two to one on the mill. The size of this engine was determined after some special tests had been made by Prof. Wm. Trinks of the Carnegie Institute of Technology, and has proved to be of just the right capacity.

This new type of mill did in practice all or more than was expected of it, as it has made very uniform gages, rolling plates 16 ft. wide down to $^3/_8$ in. gage, for the sides and crowns of locomotive boilers, with comparatively little difference in thickness between the edge and the center.

The cast-steel supporting rolls, 50 in. in diameter, furnished the strength and stiffness, while the chilled-iron working rolls, 34 in. in diameter, gave the desired finish, and were free from the spring and over-strain usually resulting from the customary type of mill. One of the features of this design is that the working rolls, which come into contact with the hot metal, and hence are subjected to heavy internal expansion strains, are freed from the burden of the transverse stress and, consequently, are less liable to breakage, while the large rolls, made of stronger material, are also not required to come into contact with the hot metal, and are free from consequent internal strains caused by the heating of the surface, and are in better condition thus to do their own part of the work of carrying the transverse bending stresses.

The size of the mill required a special design of housings, each housing being made in four parts, with suitably fitted joints strongly bolted together, and reaching across half way toward the opposite housing, thus forming the bridge for carrying the hydraulic counter-balancing mechanism and the powerful driving mechanism for the adjusting screws. The total height of the housing from the bottom of the bed plate to the top of the casing protecting the housing screws is practically 40 ft.

It is interesting to note that the main features of this mill, designed by Julian Kennedy nearly forty years ago, are now forming the basis, with suitable modifications, for the latest types of mills, for meeting the exactions of gage and finish now being so much sought after in light as well as heavy work.

R. J. Wean.[4] This discussion deals with the commercial aspect of 4-high and continuous mills. It is obvious that more

[4] Aetna Standard Engineering Co., Youngstown, Ohio.

thought and development has been put on the mechanical phase of these mills by Mr. Biggert and his company than has been given to the development of the market for the product made on this type of mill.

There is no question that steel in long lengths and in widths up to 42 in. can be rolled on hot mills of this kind, but when this product has been produced, it still remains in the form of hot strip steel and it is necessary to subject this to various finishing processes to impart the finished and physical properties required by the uses to which sheet steel is put. As these uses differ widely and are numerous, the sheet-steel industry is one of specialties.

The great diversity of uses, and the various modifications in treatment during the processes of manufacture required to adapt sheets to these uses make up a very long list of products. It is very unusual to have an extremely wide range of these various sheet grades made in one plant. Therefore, it cannot be expected that the operators of continuous 4-high mills can afford to finish this material into the wide ramification of grades required to serve the sheet industry.

The installation and operation of continuous 4-high mills have affected the sheet-steel market to such an extent that selling prices are much lower than they should be for either the sheet-steel producer or the producer of wide strip steel. They have been competing in the same market, whereas it appears as though they might serve each other to supply the same market on a non-competitive basis.

Would it not be better for the producer of wide strip steel to furnish the sheet-steel industry with material rolled down to 12, 14, or 16 gage in the form of hot strip steel and permit the experienced sheet-steel manufacturer to finish this material into the various grades required by the sheet consumers?

In this way there would be sufficient tonnage available for the wide-strip-steel operator to keep his mill in continuous operation and still make use of the existing sheet-steel finishing capacity in this country.

This same application can be made to the manufacturer of tin plate, as witnessed by the installation of one of these mills for the production of tin-mill breakdowns alone.

Surely the development of this market is worth considerable thought. The cooperation of the wide-strip producer and the sheet-steel producer would not only work out to the economic advantage of both, but to the entire steel industry as well, and most certainly to the stockholders who have invested their money in these companies.

# Destruction Test of a 66-In. Forged Steel Penstock Pipe

By JOHN L. COX,[1] PHILADELPHIA, PA.

*The section of pipe tested is representative of a portion of one section of the penstock of the Big Creek Power Plant No. 2, near Los Angeles, Calif., of the Southern California Edison Co., with the object of determining the elastic limit and ultimate strength, as well as the deformation and behavior under high pressure.*

*Details and specifications of the pipe section are given as well as a description of the test arrangements and measuring apparatus. The test is described and the results are given in tabular and graphic form.*

*The pipe reached its elastic limit at a pressure of 2150 lb. corresponding to a tangential stress of 25,000 lb. per sq. in. in the steel of the walls, the measured proportional limit of the steel at the ends being 24,500 lb. The pipe failed at a pressure of 5300 lb., which, by the approximation of the extended Birnie formula, would correspond to a fiber stress of 62,000 lb. per sq. in., compared with an actual tensile strength of 67,750 lb. The external expansion was 6 in. in diameter, or 8.3 per cent. The internal expansion was 6-3/8 in. in diameter or 9.63 per cent. The mean expansion of the wall was 8.96 per cent. The reduction in wall thickness at the mid-length of the pipe at the fracture was 3/16 in. or 6.25 per cent. The paper closes with a discussion of the results of the test.*

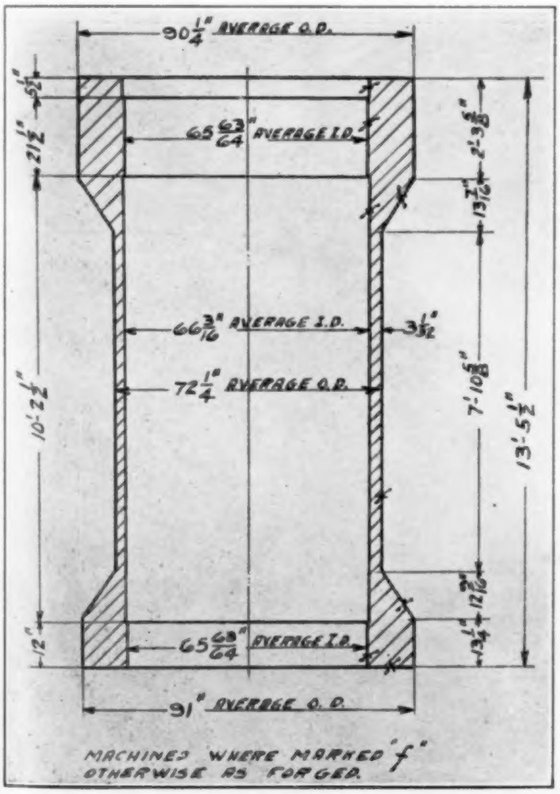

FIG. 1 SKETCH SHOWING DIMENSIONS OF THE PIPE BEFORE THE TEST

(Machined where marked "*f*;" otherwise as forged.)

### THE PROBLEM

THE Southern California Edison Company is building a high-head hydroelectric station at Big Creek Power Plant No. 2 near Fresno, California. At high water level the total head above the nozzles is 2419 ft., corresponding to a water pressure of 1050 lb. per sq. in.

The penstock consists of a single line of riveted or welded pipe running from the intake to a point where the head is 1644 ft., corresponding to a pressure of 715 lb. per sq. in. Below that point it is a 66-in. line 1682 ft. long, dividing into two 48-in. lines each 80 ft. long, subdividing again into four 34-in. lines each 60 ft. long, which run to the nozzles. The total length of the penstock is 6480 ft. of direct line, not including laterals.

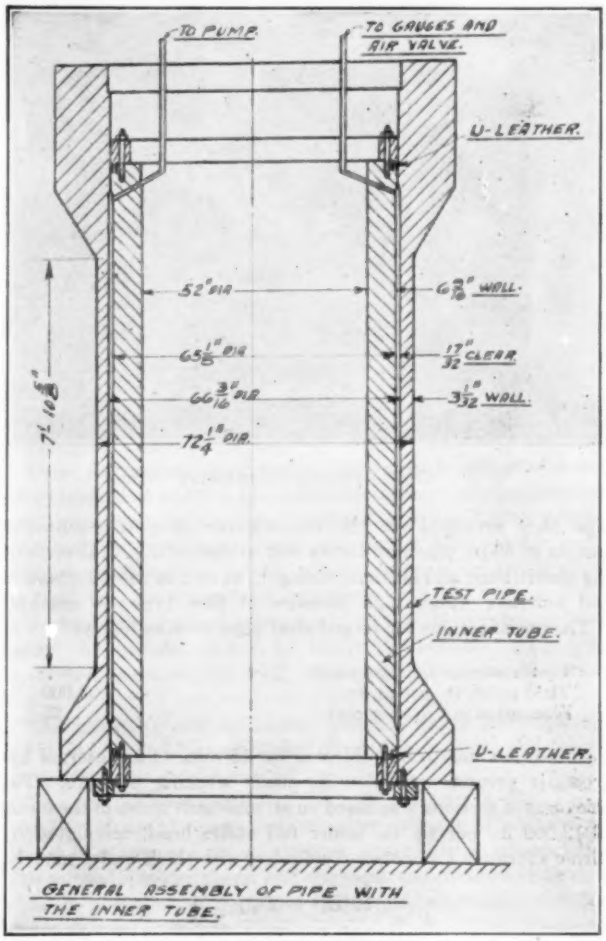

FIG. 2 GENERAL ASSEMBLY OF PIPE WITH THE INNER TUBE

Owing to the high head and to some experience with brittle pipe bursting without appreciable expansion, the company's en-

[1] The Midvale Company.

Presented at the Annual Meeting, New York, December 5 to 8, 1927, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

gineers specified for the higher-pressure section of the line (that above 715 lb. pressure) the use of forged-steel sections with integral coupling flanges, but before contracting for this type of

FIG. 3 FITTING UP THE PIPE

pipe they arranged for the manufacture of a representative section of 66-in. pipe and for its test to destruction to determine the elastic limit and ultimate strength, as well as the deformation and behavior under high pressure of this type of conduit.

The specifications for forged-steel pipe were as follows:

| | |
|---|---|
| Tensile strength, lb. per sq. in. | 62,000 |
| Yield point, lb. per sq. in. | 35,000 |
| Elongation in 2 in., per cent | 25 |

Each section was to be subjected for 15 min. to an internal hydrostatic pressure of twice its static working pressure. The thickness of sections was based on an allowable stress in the metal of 12,000 lb. per sq. in. under full static head, calculated by Birnie's formula for open-end cylinders with thick walls: namely,

$$P = \frac{10(D_1^2 - D_2^2)}{13D_1^2 + 7D_2^2} \times S$$

where $P$ = internal pressure in pounds per square inch
$D_1$ = outside diameter in inches
$D_2$ = inside diameter in inches, and
$S$ = fiber stress in pounds per square inch.

For reasons of economy the body of the test pipe was reduced in length to 8 ft., that being considered sufficiently long to avoid reinforcement of the mid-length by the end flanges—a view that later proved to be correct.

Fig. 1 shows the design adopted for this representative forging. The pipe had an average internal diameter of $66^3/_{16}$ in., an average wall thickness of $3^1/_{32}$ in. over a length of $94^5/_8$ in., and a heavy flange at each end.

## MANUFACTURE

To this design a forging was made from a 63-in. octagon ingot of acid open-hearth steel of the following composition:

| | |
|---|---|
| Carbon | 0.29 |
| Manganese | 0.51 |
| Phosphorus | 0.024 |
| Sulphur | 0.042 |
| Silicon | 0.21 |

After reheating, the ingot was cropped, punched, expanded, and forged under a 9000-ton hydraulic press, then lightly annealed. The average physical properties obtained on transverse test bars taken from the heavy section of the ends, about 13 in. thick, gave the following results:

| | |
|---|---|
| Tensile strength, lb. per sq. in. | 67,750 |
| Yield point, lb. per sq. in. | 37,000 |
| Proportional limit, lb. per sq. in. | 24,500 |
| Elongation in 2 in., per cent | 31.2 |
| Reduction of area, per cent | 41.5 |

## TEST ARRANGEMENTS

To reduce the volume of the water space at test and to simulate conditions of actual service, there was arranged to be inserted in the test pipe a thick-walled cylinder having ends closely fitting

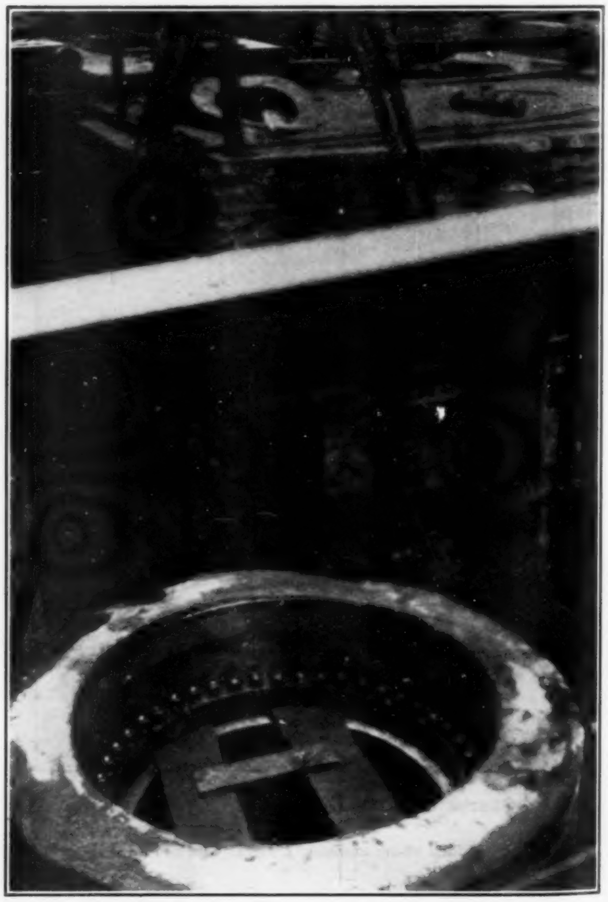

FIG. 4 UPPER END OF PIPE

the bore of the pipe and fitted with U-leathers. A slight reduction in diameter of the inner cylinder between its fitted ends and a slight increase in diameter of the pipe between the same points, provided a small annular space for the high-pressure water.

Fig. 2 shows how the pipe section was fitted with its inner cylinder. This had an average inside diameter of 52 in., an outside diameter of $65^1/_8$ in., and an elastic limit of 38,300 lb. per sq. in.

The heavy flange at each end of the pipe was intended to prevent failure of the U-leathers by an increase in the clearance between inner cylinder and pipe through expansion of the latter under pressure.

Fig. 3 shows the pipe being fitted up, and Fig. 4 the upper end of the pipe with the retaining ring of its U-leather.

Pressure was supplied by a motor-driven test pump with a capacity of two gallons per minute up to 6000 lb. pressure. There were provided the following measuring instruments:

One indicating pressure gage, range 0 to 4000 lb., read for pressures up to 3500 lb. for accurate determination of the elastic limit of the pipe. This was shut off at the higher pressures.

One indicating pressure gage, range 0 to 10,000 lb., read for pressures from 3500 lb. up to final pressure.

One recording pressure gage, range 0 to 15,000 lb., one revolution in two hours, operating during the entire test.

Four Ames indicating dials, range 0 to 0.250 in., measuring radial expansions at four points 90 deg. apart at mid-length of the pipe, read for pressures up to 2600 lb.

Four electric expansion indicators, range 0 to 8 in., reading to $^1/_4$ in., each consisting of a guided bar forced at one end against the outside of the pipe by a spring and carrying on the other end a slide passing over a series of closely spaced contacts, each contact connected to one of a series of indicating lamps mounted on a board with corresponding indicated expansions marked on an adjoining scale. These indicators were applied at the same points as the Ames dials when the latter were removed,

Fig. 5 Electric Expansion Indicator—Contacting End

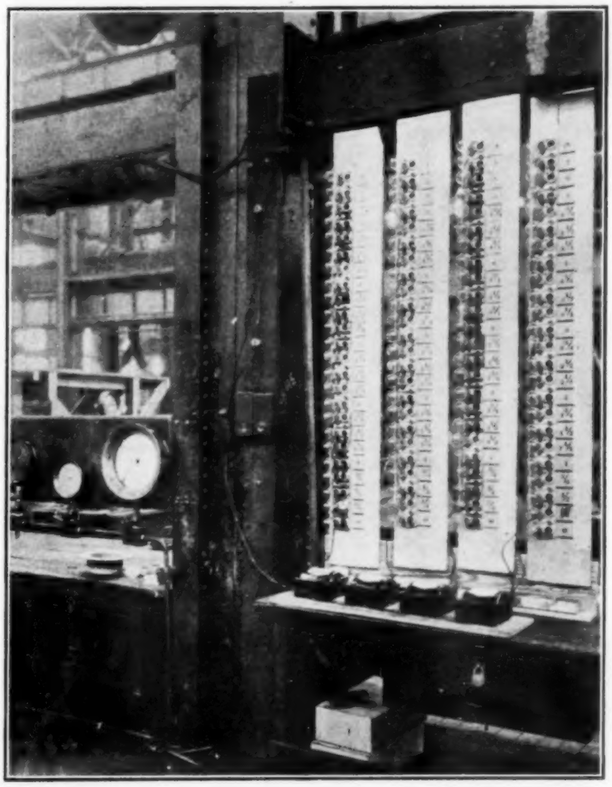

Fig. 6 Electric Expansion Indicator—Indicating End

and measured the radial expansion from 2600 lb. up to the bursting pressure. Fig. 5 shows the contacting end and Fig. 6 the indicating end of these devices.

There were also:

Three mechanical expansion indicators, each formed of a steel wire fastened at one end to a fixed object near the pipe, wrapped one turn around the lubricated body of the pipe and, after running over suitably arranged pulleys, suspending at the other end a counterweight with a pointer indicating on a vertical scale at its side the circumferential expansion of the pipe. These indicators were applied respectively at 6 in. below the top, 6 in. below the middle, and 6 in. above the bottom of the $3^1/_{32}$-in.-thick portion of the wall, and operated during the entire test.

The recording and indicating pressure gages were specially calibrated by the Bureau of Standards for this test, and the observed readings were corrected accordingly.

The general arrangement of the test is shown in Fig. 7. To avoid accidents the pipe with its inner cylinder in position was placed in a concrete pit and the pit covered with armor plates. The pump, pressure gages, and the expansion indicating devices, with the exception of the Ames dials, were mounted on the floor above at a safe distance.

The Ames dials and, later, the contactors of the electric expansion indicators were mounted on a rigid structural-steel frame surrounding the pipe and resting independently on the concrete floor of the pit, upon which the pipe was also firmly supported on end. Fig. 8 shows this frame with the Ames dials in position, and Fig. 9 shows the electrical gages in position after removal of the dials at 2600 lb. pressure.

gineers specified for the higher-pressure section of the line (that above 715 lb. pressure) the use of forged-steel sections with integral coupling flanges, but before contracting for this type of

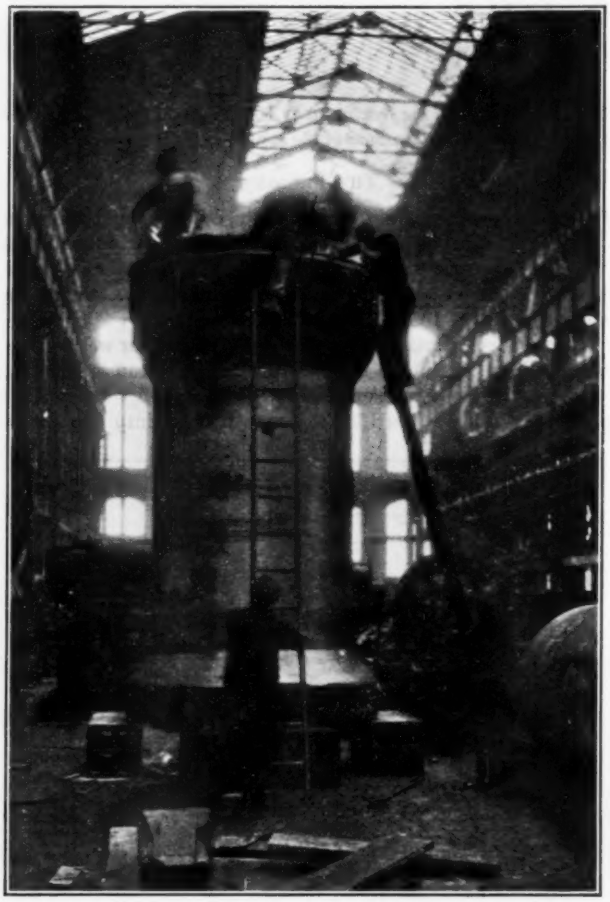

Fig. 3 Fitting Up the Pipe

pipe they arranged for the manufacture of a representative section of 66-in. pipe and for its test to destruction to determine the elastic limit and ultimate strength, as well as the deformation and behavior under high pressure of this type of conduit.

The specifications for forged-steel pipe were as follows:

| | |
|---|---|
| Tensile strength, lb. per sq. in. | 62,000 |
| Yield point, lb. per sq. in. | 35,000 |
| Elongation in 2 in., per cent | 25 |

Each section was to be subjected for 15 min. to an internal hydrostatic pressure of twice its static working pressure. The thickness of sections was based on an allowable stress in the metal of 12,000 lb. per sq. in. under full static head, calculated by Birnie's formula for open-end cylinders with thick walls: namely,

$$P = \frac{10(D_1^2 - D_2^2)}{13D_1^2 + 7D_2^2} \times S$$

where $P$ = internal pressure in pounds per square inch
$D_1$ = outside diameter in inches
$D_2$ = inside diameter in inches, and
$S$ = fiber stress in pounds per square inch.

For reasons of economy the body of the test pipe was reduced in length to 8 ft., that being considered sufficiently long to avoid reinforcement of the mid-length by the end flanges—a view that later proved to be correct.

Fig. 1 shows the design adopted for this representative forging. The pipe had an average internal diameter of $66^3/_{16}$ in., an average wall thickness of $3^1/_{32}$ in. over a length of $94^5/_8$ in., and a heavy flange at each end.

### Manufacture

To this design a forging was made from a 63-in. octagon ingot of acid open-hearth steel of the following composition:

| | |
|---|---|
| Carbon | 0.29 |
| Manganese | 0.51 |
| Phosphorus | 0.024 |
| Sulphur | 0.042 |
| Silicon | 0.21 |

After reheating, the ingot was cropped, punched, expanded, and forged under a 9000-ton hydraulic press, then lightly annealed. The average physical properties obtained on transverse test bars taken from the heavy section of the ends, about 13 in. thick, gave the following results:

| | |
|---|---|
| Tensile strength, lb. per sq. in. | 67,750 |
| Yield point, lb. per sq. in. | 37,000 |
| Proportional limit, lb. per sq. in. | 24,500 |
| Elongation in 2 in., per cent | 31.2 |
| Reduction of area, per cent | 41.5 |

### Test Arrangements

To reduce the volume of the water space at test and to simulate conditions of actual service, there was arranged to be inserted in the test pipe a thick-walled cylinder having ends closely fitting

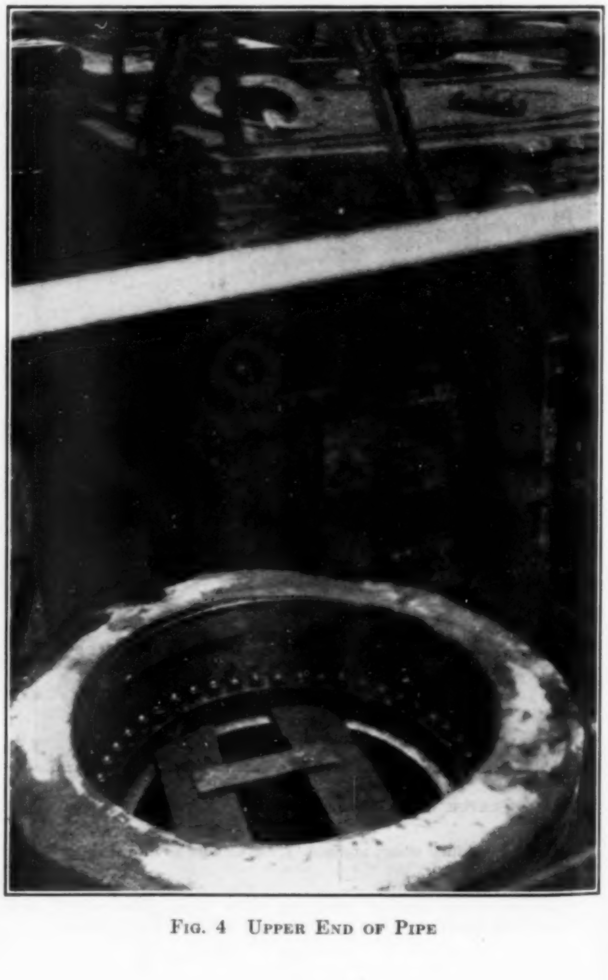

Fig. 4 Upper End of Pipe

the bore of the pipe and fitted with U-leathers. A slight reduction in diameter of the inner cylinder between its fitted ends and a slight increase in diameter of the pipe between the same points, provided a small annular space for the high-pressure water.

Fig. 2 shows how the pipe section was fitted with its inner cylinder. This had an average inside diameter of 52 in., an outside diameter of $65^1/_8$ in., and an elastic limit of 38,300 lb. per sq. in.

The heavy flange at each end of the pipe was intended to prevent failure of the U-leathers by an increase in the clearance between inner cylinder and pipe through expansion of the latter under pressure.

Fig. 3 shows the pipe being fitted up, and Fig. 4 the upper end of the pipe with the retaining ring of its U-leather.

Pressure was supplied by a motor-driven test pump with a capacity of two gallons per minute up to 6000 lb. pressure.

There were provided the following measuring instruments:

One indicating pressure gage, range 0 to 4000 lb., read for pressures up to 3500 lb. for accurate determination of the elastic limit of the pipe. This was shut off at the higher pressures.

One indicating pressure gage, range 0 to 10,000 lb., read for pressures from 3500 lb. up to final pressure.

One recording pressure gage, range 0 to 15,000 lb., one revolution in two hours, operating during the entire test.

Four Ames indicating dials, range 0 to 0.250 in., measuring radial expansions at four points 90 deg. apart at mid-length of the pipe, read for pressures up to 2600 lb.

Four electric expansion indicators, range 0 to 8 in., reading to $^1/_4$ in., each consisting of a guided bar forced at one end against the outside of the pipe by a spring and carrying on the other end a slide passing over a series of closely spaced contacts, each contact connected to one of a series of indicating lamps mounted on a board with corresponding indicated expansions marked on an adjoining scale. These indicators were applied at the same points as the Ames dials when the latter were removed, and measured the radial expansion from 2600 lb. up to the bursting pressure. Fig. 5 shows the contacting end and Fig. 6 the indicating end of these devices.

Fig. 5 Electric Expansion Indicator—Contacting End

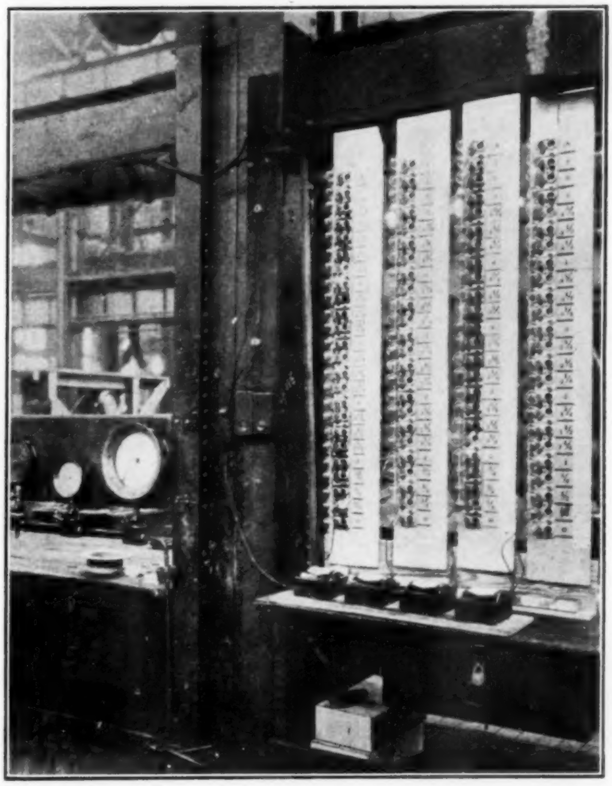

Fig. 6 Electric Expansion Indicator—Indicating End

There were also:

Three mechanical expansion indicators, each formed of a steel wire fastened at one end to a fixed object near the pipe, wrapped one turn around the lubricated body of the pipe and, after running over suitably arranged pulleys, suspending at the other end a counterweight with a pointer indicating on a vertical scale at its side the circumferential expansion of the pipe. These indicators were applied respectively at 6 in. below the top, 6 in. below the middle, and 6 in. above the bottom of the $3^1/_{32}$-in.-thick portion of the wall, and operated during the entire test.

The recording and indicating pressure gages were specially calibrated by the Bureau of Standards for this test, and the observed readings were corrected accordingly.

The general arrangement of the test is shown in Fig. 7. To avoid accidents the pipe with its inner cylinder in position was placed in a concrete pit and the pit covered with armor plates. The pump, pressure gages, and the expansion indicating devices, with the exception of the Ames dials, were mounted on the floor above at a safe distance.

The Ames dials and, later, the contactors of the electric expansion indicators were mounted on a rigid structural-steel frame surrounding the pipe and resting independently on the concrete floor of the pit, upon which the pipe was also firmly supported on end. Fig. 8 shows this frame with the Ames dials in position, and Fig. 9 shows the electrical gages in position after removal of the dials at 2600 lb. pressure.

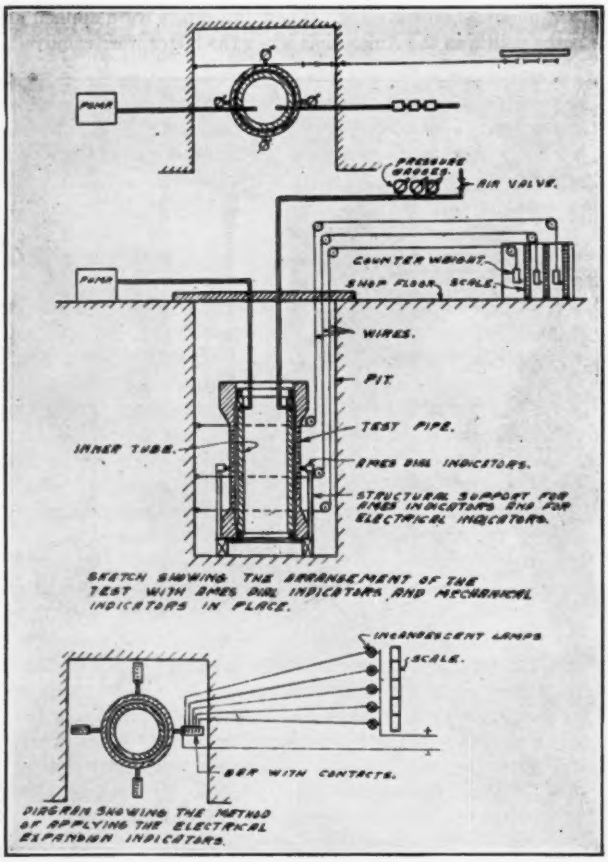

FIG. 7 SKETCH SHOWING (*a*) ARRANGEMENT OF TEST WITH AMES DIAL INDICATORS AND MECHANICAL INDICATORS IN PLACE, AND (*b*) METHOD OF APPLYING THE ELECTRICAL EXPANSION INDICATORS

## THE TEST

A preliminary test under a pressure of 1800 lb. developing no leaks of the U-leathers or at the joints of the piping, the official test began at 10:20 a.m. the following day in the presence of engineers of Messrs. Stone & Webster, representing the purchaser, and representatives of The Midvale Company and of the Bethlehem Steel Company.

The system forefilled and the air valve closed, pressure was gradually raised to 2600 lb., readings of the radial expansions being taken with the Ames dial indicators at pressures of 500, 750, 1000, 1250, 1500, 1600, 1700, 1800, 1900, 2000, 2100, 2200, 2300, 2350, 2400, 2500, and 2600 lb. per sq. in. As the readings were taken, two curves were plotted, each representing the average radial expansion of two diametrically opposite points on the pipe as a function of the pressure.

At 2600 lb. pressure it was evident from both curves that the elastic limit had been certainly passed, the pump was stopped, the dial indicators removed, and the electrical indicators put in their place. The pressure was again increased. At 11:25 a.m. at 3400 lb. pressure, a pipe joint leaked, requiring a relief of pressure to make repairs.

At 12:04 p.m., the pump was again started and expansions recorded up to a pressure of 4200 lb., when, at 12:35 p.m., a leaking joint compelled a second interruption. Repairs were completed at 1:50 p.m., the pump started and expansion readings taken up to 3:03 p.m., when at a pressure of 5300 lb. per sq. in. and with a loud report, the pipe burst.

Figs. 10, 11, and 12 show the manner in which the fracture occurred, as predicted by Dr. F. C. Langenburg, consulting metallurgist of the Watertown Arsenal, from the results of his experiments on gun forgings.

The crack extended entirely through the bottom flange, with a crack at right angles to it at the point of stress concentration between the body and the bevel of the flange. The two arms of the V-shaped crack at the upper end partly encircled the forging there in the same region of maximum stress and then bent downward, as will be seen in Fig. 4, nearly meeting at the opposite side of the forging.

## RESULTS

On Fig. 13 are shown curves plotted from the readings of the various devices for measuring expansion. They represent the diametral expansion of the pipe as a function of the pressure, throughout the entire period of the test.

From 0 to 2600 lb. pressure the left curve shows the average of the readings from the four Ames dial indicators. At that pressure they were removed, the electric expansion indicators were emplaced, and thereafter the latter gave four closely parallel curves which were averaged and are shown as one curve.

The readings of the two mechanical indicators near the ends of the pipe were closely alike and, similarly averaged, are shown as one curve.

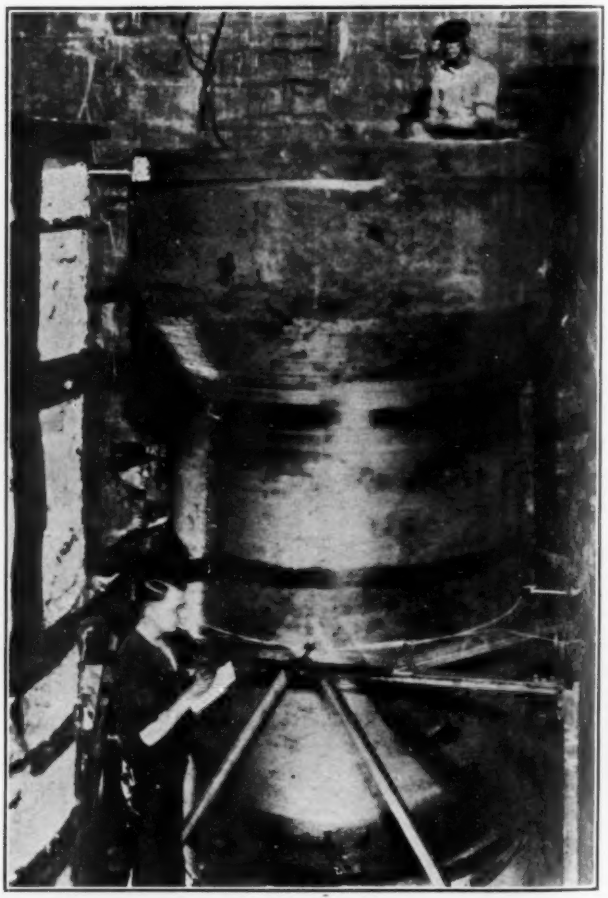

FIG. 8 READING THE AMES DIALS

The straight dotted line shows anticipated diametral expansions up to 2500 lb. internal pressure, based on stresses derived by Birnie's formula and a modulus of elasticity of 30,000,000 for the steel.

The expansion curves show clearly that the proportional limit of the steel was reached at 2150 lb. pressure, producing, as shown in Fig. 14, a tangential stress in the pipe wall of 25,000 lb. per sq. in. This agrees closely with the 24,500 lb. proportional limit of the transverse-test bar.

The soundness of the formula is further shown by the substantial agreement of the actual and anticipated expansions.

Fig. 14 shows the tangential stresses in the walls of the cylinder as a function of the pressure, using the Birnie formula and disregarding the limitation of the formula to stresses within the proportional limit.

According to this curve, the wall stress produced by the bursting pressure of 5300 lb. would be 62,000 lb. per sq. in. This is somewhat less than the tensile strength of the transverse-test bar, 67,750 lb. The difference shows the error of the formula when extended beyond its recognized limitations, while emphasizing by its small amount the unexpectedly close approximation of the formula to the truth.

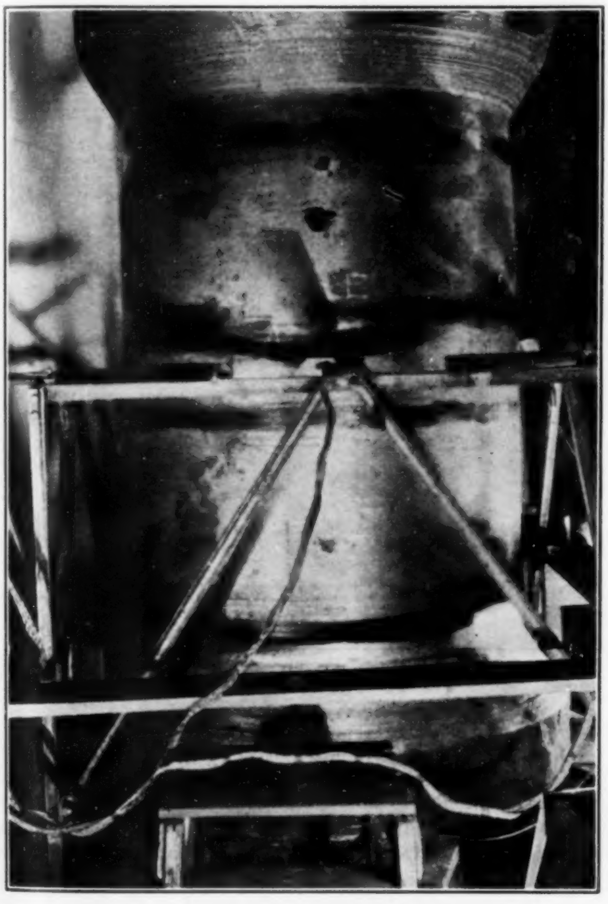

FIG. 9 ELECTRICAL INDICATOR IN PLACE

As previously stated, transverse-test bars cut from the metal of the flanges of the pipe for test averaged:

| | |
|---|---|
| Tensile strength, lb. per sq. in. | 67,750 |
| Yield point, lb. per sq. in. | 37,000 |
| Proportional limit, lb. per sq. in. | 24,500 |
| Elongation in 2 in., per cent | 31.2 |
| Reduction of area, per cent | 41.5 |

After the test transverse-test bars were taken at the root of the lower flange where the expansion was 2 per cent due to the restraining influence of the flange, the results averaging:

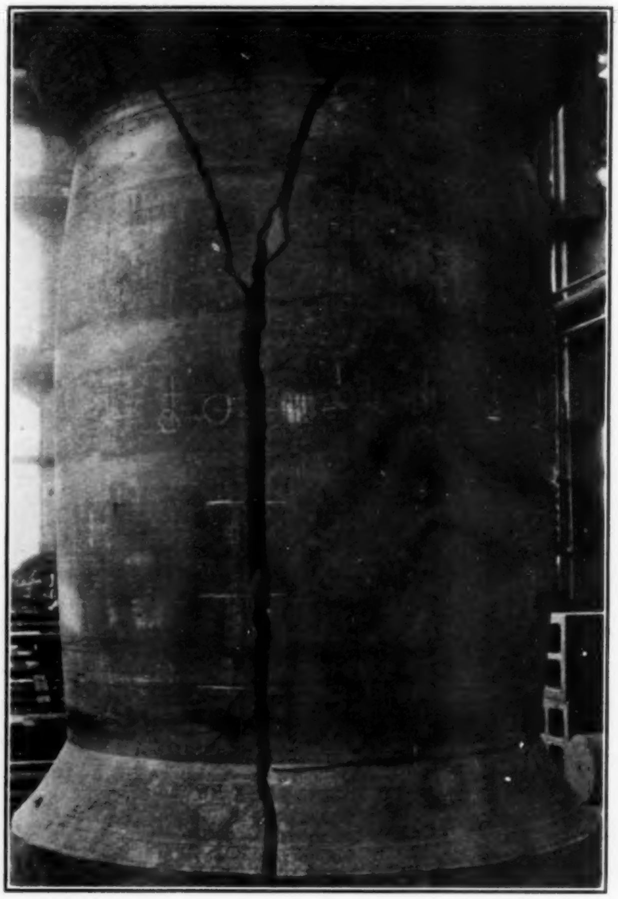

FIG. 10 FRACTURE, FRONT VIEW

| | |
|---|---|
| Tensile strength, lb. per sq. in. | 64,000 |
| Yield point, lb. per sq. in. | 43,500 |
| Proportional limit, lb. per sq. in. | 33,500 |
| Elongation in 2 in., per cent | 26.1 |
| Reduction of area, per cent | 53.7 |

A transverse-test bar was also taken at the mid-length of the forging where the expansion averaged 8.96 per cent which gave:

| | |
|---|---|
| Tensile strength, lb. per sq. in. | 75,000 |
| Yield point, lb. per sq. in. | 68,000 |
| Proportional limit, lb. per sq. in. | 50,000 |
| Elongation in 2 in., per cent | 17.0 |
| Reduction of area, per cent | 37.2 |

These figures show the extent to which the metal was work-hardened by the cold-working to which it had been subjected.

An examination of the readings of the electrical and mechanical indicators taken beyond the proportional limit of the steel shows a fairly close agreement, considering their relative positions—at the center and 6 in. below it—and the difference in their methods of operation. They give a diametral expansion at the mid-length of the pipe of somewhat over 6 in. at the moment of failure. The circumferential measurements taken after fracture give a diametral expansion of $6^1/_4$ in. as shown in Fig. 15. In the calculations that follow, 6 in. is taken as being certain.

The form and extent of the fracture and the final shape of the pipe are also shown in this sketch. The main crack occurred in the quadrant where the wall was originally thinnest.

The original wall thickness of the middle of the pipe in the quadrant of rupture was 3 in., reduced to $2^{13}/_{16}$ in. after test,

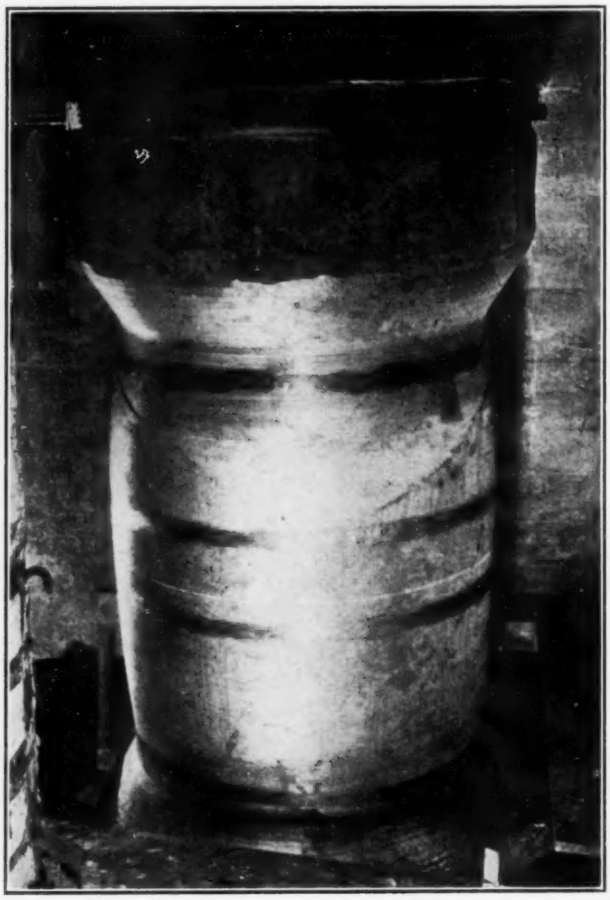

FIG. 11 FRACTURE, REAR VIEW

FIG. 12 FRACTURE, SIDE VIEW

giving a reduction in wall thickness of $^3/_{16}$ in. or 6.25 per cent.

The initial outside diameter of the pipe was $72^1/_4$ in., the final diameter $72^1/_4$ in. + 6 in. = $78^1/_4$ in.; corresponding to an expansion of 8.3 per cent.

The initial inside diameter of the pipe was $66^3/_{16}$ in., and after test $66^3/_{16}$ in. + 6 in. expansion + $^3/_8$-in. reduction in two wall thicknesses = $72^9/_{16}$ in., giving an inner diametral expansion of 9.63 per cent. The mean expansion was therefore $(8.3 + 9.63) \div 2 = 8.96$ per cent.

The burst pipe was cylindrical for a distance of from 4 in. to $7^1/_2$ in. at the mid-length, indicating that the section there was not influenced by the proximity of the reinforced ends, and that the effect produced there would have continued for any additional length the pipe might have had.

### Summary of Results

The pipe reached its elastic limit at a pressure of 2150 lb. corresponding to a tangential stress of 25,000 lb. per sq. in. in the steel of the walls, the measured proportional limit of the steel at the ends being 24,500 lb.

The pipe failed at a pressure of 5300 lb. which, by the approximation of the extended Birnie formula, would correspond to a fiber stress of 62,000 lb. per sq. in., compared with an actual tensile strength of 67,750 lb.

The external expansion in diameter was 6 in., or 8.3 per cent. The internal expansion was $6^3/_8$ in. or 9.63 per cent. The mean expansion of the wall was 8.96 per cent. The reduction in wall thickness at the mid-length of the pipe at the fracture was $^3/_{16}$ in. or 6.25 per cent.

### Observations

It is seldom that an opportunity is afforded engineers for comparing the elastic and breaking strengths of a large forging with that of its representative test bars—and it is encouraging to note that they appear to be in such good accord. A foundation is laid for confidence that test bars properly located will truly indicate the average behavior of the metal in the large forging from which they may be taken.

It appears that an internal pressure producing a calculated stress practically equal to the proportional limit of its metal can be withstood without permanent deformation by a seamless forged-steel pipe; and that it may fail at about the pressure given by the Birnie formula arbitrarily extended to the ultimate strength.

Ductility has always been considered of great advantage in the walls of any vessel as enabling them to yield to sudden overpowering stress and so reduce the severity of the shock. There is also great gain in the substitution of swelling or splitting of the walls,

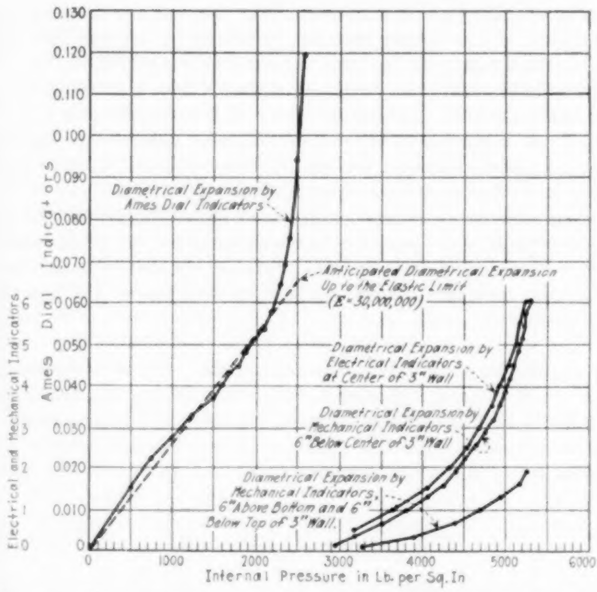

FIG. 13 CURVES PLOTTED FROM READINGS OF THE VARIOUS DEVICES FOR MEASURING EXPANSION, AND SHOWING DIAMETRAL EXPANSION OF PIPE AS A FUNCTION OF PRESSURE

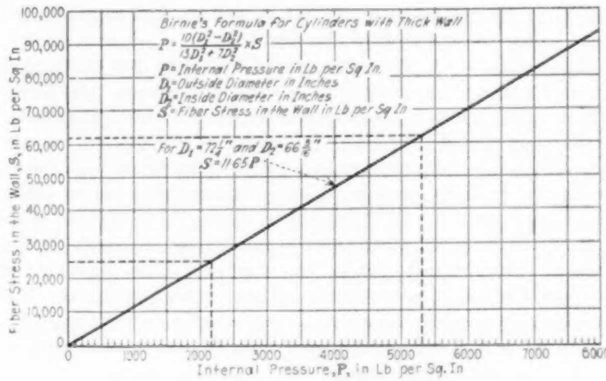

FIG. 14 TANGENTIAL STRESSES IN WALLS OF CYLINDER AS A FUNCTION OF THE PRESSURE, USING BIRNIE FORMULA AND DISREGARDING ITS LIMITATION TO STRESSES WITHIN THE PROPORTIONAL LIMIT

with gradual relief of pressure, for the explosive relief of shattering.

A further advantage lies in the visual evidence of distress given by a positive swelling, enabling replacement of a part before its destruction occurs.

The experiment just reported indicates another advantage not usually recognized.

Within recent years much progress has been made in the construction of light ordnance by the process of autofrettage—the preliminary expansion by hydraulic pressure of an underbored gun. By a stretching beyond its elastic limit the metal of the bore is, on relief of pressure, left in a state of initial compression while the outer layers are in moderate initial tension, the effect being similar to that of a built-up gun. The usual amount of initial expansion is about 5 per cent of the diameter.

The same effect has been produced in the walls of this representative pipe. The stress produced in the original wall by 1050 lb., the highest pressure in the system, would be about 12,500 lb., giving a factor of safety of 2 compared with the original proportional limit in the steel of 24,500.

The expanded pipe, having a proportional limit of 50,000, would carry with the same factor of safety an internal pressure of 1840 lb. Therefore, just before bursting the expanded pipe was as safe, theoretically, for 1840 lb. pressure as a brittle pipe for 1050 lb. pressure.

The pronounced expansion shown by the seamless forged-steel pipe tested indicates both that it is an eminently safe type of pipe, able to bear excessive loads without fracture, and that it may be relied upon to give ample warning of danger in case of weakening through corrosion or otherwise.

## Discussion

E. O. WATERS.[2] The test reported by the author is extremely interesting as a check on existing theories of the strength of cylinders. The fact that the ultimate strength as computed by Birnie's formula falls considerably below that obtained from the test bars is of far less significance than the close agreement between the actual and theoretical stretch within the elastic limit. The curves in Fig. 13 (below the elastic limit) prove unmistakably the soundness of a formula that is based on maximum strains and takes account of the interrelation of the principal stresses, in accordance with St. Venant's hypothesis.

The writer has had recent occasion to investigate the stresses in pipe flanges, and wishes to state emphatically that the St. Venant principle, when applied to a theoretical analysis of flanges, gave a most satisfying agreement with the deflections obtained by test. In the present instance, the expansion calculated from the thin-cylinder formula would be appreciably less than that given by the dotted line in Fig. 13, i.e., 0.050 in. or less at 2000 lb. per sq. in. internal pressure, depending upon what diameter is used; and the ultimate strength

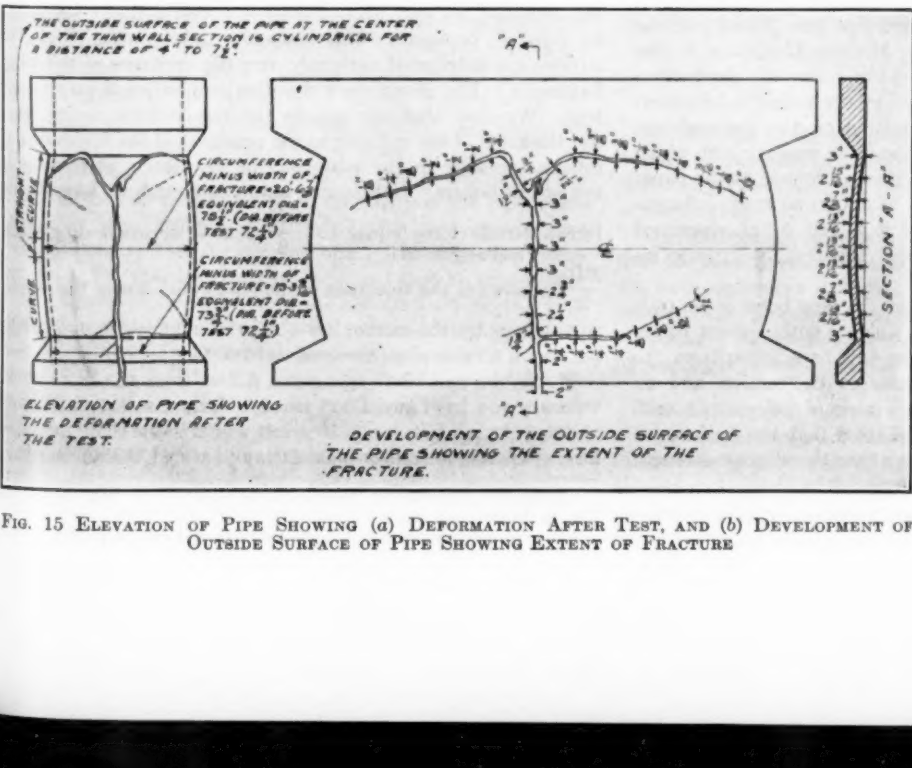

FIG. 15 ELEVATION OF PIPE SHOWING (a) DEFORMATION AFTER TEST, AND (b) DEVELOPMENT OF OUTSIDE SURFACE OF PIPE SHOWING EXTENT OF FRACTURE

[2] Assistant Professor of Mechanical Engineering, Yale University, New Haven, Conn. Mem. A.S.M.E.

would figure out as about 57,900 lb. per sq. in., some 16 per cent below the strength of the test bars.

The author's computed strength of 62,000 lb. per sq. in. was evidently figured on the original diameter of the pipe. But allowing for the increase in total hydrostatic load due to the expanded inside diameter of the pipe at the instant of failure, it is easy to show that the ultimate strength is 67,600 lb. per sq. in.; this is computed without assuming any shrinkage in wall thickness, which obviously would be in error, as it would be akin to computing the ultimate strength of a tensile-test specimen on the basis of the reduced area of the fracture. This figure, while unimportant, may be considered as corroboration of the other results and a further proof of the soundness of the formulas.

Checking the test results according to the maximum-shear theory, we have the following:

Average shearing strength of test bars, 67,750 ÷ 2 = 33,875 lb. per sq. in.

Maximum radial stress in pipe, 5300 lb. per sq. in., compression.

Maximum hoop stress, based on expanded pipe, with no reduction in wall thickness, 66,029 lb. per sq. in., tension.

Corresponding shear stress, (66,029 + 5300) ÷ 2 = 35,663 lb. per sq. in. This is not as good an agreement as the one just given on the basis of the maximum-strain theory using the expanded inside diameter, but is a better correlation than that given by the maximum-strain theory based on the original diameter.

H. L. Doolittle.[3] In the design of the penstock for the new Big Creek Power Plant No. 2 of the Southern California Edison Company, several interesting and difficult problems were encountered. This plant will contain two 56,000-hp. units operating under a head of approximately 2400 ft. Economic studies showed that it would be desirable to depart from the usual practice of installing one penstock for each unit and use instead a single pipe line to a point adjacent to the power house where laterals would be installed to branch to the two units.

The use of a single line to supply these two large units under this high head required a diameter of 66 in. at the bottom with a wall thickness of 3 in. After making an investigation of the different ways in which this pipe could be built, it was finally decided to use seamless steel forgings with integrally forged flanges. As this company had never used any material of this description, it was stated in the contract that a piece of pipe, representing the heaviest section, should be tested to destruction before proceeding with the manufacture of the penstock proper.

While equal contracts for this forged pipe were placed with the Bethlehem Steel Company and the Midvale Company, it was decided to have the Midvale Company make the destruction test. This test is very ably described by the author in his paper, and his company is to be congratulated on the thoroughness with which they carried out the test and the rapidity with which all of the work in connection therewith was done. As the paper shows, every precaution was taken to obtain as much information as possible from the test, and it is felt by all concerned that the information obtained amply justified the expense involved.

It was very gratifying to note that the pipe burst at an ultimate stress of 62,000 lb. per sq. in., which is within about 10 per cent of the ultimate strength of the test bars taken from the forging. Observations on other tests to destruction and on penstocks that have failed in service, made of different material and by different processes, have indicated that the failures occurred at stresses very materially lower than the ultimate strength of the test bars.

[3] Chief Designing Engineer, Southern California Edison Co., Los Angeles, Calif. Mem. A.S.M.E.

Another very gratifying result of the test was the proof of the ductility of this forged material, indicated by a 9 per cent increase in diameter at the time of failure. In addition to this increase in diameter, the thickness reduced a little over 6 per cent. It is felt that this ductility is a very desirable quality in a penstock, as operating conditions are likely to subject the pipe to severe water hammer. The more brittle the metal, the less able it is to withstand these sudden shocks.

The observations made in the paper regarding the increase in the strength of the pipe due to its expanding under pressure are of interest, but it is doubtful if operating companies would take this into consideration and reduce the thickness of the pipe on that account.

A. M. Wahl.[4] The author has applied the Birnie formula for stress in thick cylinders to this case. It is also instructive to apply Lamé's formula[5] for thick cylinders to this pipe and see how it checks with the Birnie formula. Lamé's formula is, using the notation of the paper,

$$S = \frac{PD_2^2}{D_1^2 - D_2^2}\left(1 + \frac{D_1^2}{4R^2}\right) \qquad [1]$$

where $R$ is the distance from the axis of the thick cylinder at which the stress $S$ exists. It is clear from this formula that the stress is a maximum at the inner edge, i.e., when $R = D_2$. This maximum value is

$$S_{\text{max.}} = \frac{PD_2^2}{D_1^2 - D_2^2}\left(1 + \frac{D_1^2}{D_2^2}\right) \qquad [2]$$

Substituting in Equation [1] the dimensions given by the author we obtain, at an internal pressure of 2150 lb. per sq. in. corresponding to the elastic limit found by test, a stress distribution over the cross-section of the pipe as shown in Fig. 16. The maximum stress occurs along the inside edge and is equal to 24,650 lb. per sq. in. while the minimum stress occurs at the outside edge and is equal to 22,500 lb. per sq. in. The value of of the maximum stress obtained in this way, i.e., 24,650 lb. per sq. in., is quite close to the value of proportional limit found by the author using test pieces cut from the flange of the pipe. It also does not differ greatly from the value of 25,000 lb. per sq. in. obtained by the author using the Birnie formula. These figures indicate that both the Lamé and Birnie formulas give results quite close to the actual test results.

Since the pipe-wall thickness is quite small compared with the diameter, we may also consider it a thin cylinder subjected to internal pressure. This amounts to assuming that the stresses are distributed uniformly over the thickness of the pipe. Reference to Fig. 16 will show that this supposition is very nearly true. We may therefore equate the tensile force acting over the thickness of the cylinder to the resultant of the forces due to internal pressure in the same way as we determine stresses in cylindrical boilers. Considering unit axial length we have therefore a tensile force equal to $\frac{PD_2}{2}$ and a corresponding stress $\frac{PD_2}{2t}$, where $t$ is the thickness of the pipe wall. Using the dimensions given by the author we obtain at a pressure of 2150 lb. per sq. in. a value of stress equal to 23,500 lb. per sq. in.

It may be seen that this stress differs from the more exact values given by Lamé's and Birnie's formulas above, by only about 6 per cent or less. Hence it would seem that, for pipes having the relative dimensions of the pipe tested, it is unnecessary

[4] Research Laboratory, Westinghouse Electric & Manufacturing Co., E. Pittsburgh, Pa.

[5] See "Applied Elasticity," Timoshenko and Lessells, p. 252.

to apply thick-cylinder formulas to obtain reasonably accurate results.

It is hard for the writer to accept without qualification the statement made at the end of the paper that "the metal of the bore is, on relief of pressure, left in a state of initial compression, while the outer layers are in a state of moderate initial tension." This effect undoubtedly occurs to a considerable degree in guns when subjected initially to high pressure, but in such cases the wall thickness of the gun is quite large compared to the diameter. Hence the stress distribution below the elastic limit is somewhat as shown by the shaded area of Fig. 17, a peak of stress occurring along the bore. When stressed by internal pressure the material at the bore most quickly reaches its elastic limit. After this occurs, permanent set is produced and the peak of stress is cut off. On relieving the pressure, high residual stresses of opposite sign are induced at the bore.

On the other hand, when the stress distribution is very nearly uniform, which, as indicated by Fig. 16, was the case for this penstock pipe, there is no sharp peak of stress to be cut off as is the case with guns. Consequently no very high residual stresses can be induced. Such a case would be similar to attempting to induce high residual stresses in a tension test piece by stressing beyond the elastic limit in a tension-testing machine and then relieving the load.

There is no doubt that, as the author states, the proportional limit of the material is raised by overstraining the metal. But it must also be noted that the author's tests show that the ultimate strength of the test bars cut out after failure of the pipe did not show a corresponding increase. Hence, in view of this fact and what has been mentioned above, the writer cannot agree entirely with the statement that "just before bursting the expanded pipe was as safe theoretically for 1840 lb. pressure as a brittle one for 1050 lb. pressure."

The writer takes this statement to mean that the factors of safety against bursting for a brittle pipe at 1050 lb. pressure and for a ductile pipe at 1840 lb. would be equal. Since, as shown above, only a small amount of residual stress is induced by overstraining, and since the ultimate strength is not greatly raised by such treatment, it is possible, in the writer's opinion, that the factors of safety against bursting for the ductile pipe and the brittle pipe would not be greatly different provided the ultimate strength of both kinds of material is the same, and assuming that no stress concentration, due to holes, fillets, or other causes exists, and that no initial ellipticity of the pipe cross-section due to fabrication is present.

Since in practical pipes there is always some concentration of stress near holes, flanges, outlets, etc., the ductile pipe is superior because it will allow yielding of the material without failure at points of concentration of stress; consequently the stresses are reduced by virtue of this yielding. On the other hand, brittle materials would allow a crack to open.

A further reason for the superiority of the ductile pipe arises because of the fact that some initial ellipticity of the pipe cross-section may arise during fabrication, i.e., the cross-section may deviate somewhat from the circular form. The writer has calculated, using the analysis given in his paper,[6] that an initial ellipticity or maximum deviation from the circular form of the pipe cross-section equal to one-sixth the thickness of the pipe wall, will approximately double the maximum stress set up by internal pressure. These calculations have recently been verified by strain measurements made by the writer on large pipe bends for steam turbines. For example, it was found that in a 10-in. expansion bend for a steam turbine at points where the ellipticity was about 0.1 in., the stress in the circumferential direction due to an internal pressure alone of 1000 lb. per sq. in., varied from about 1000 lb. per sq. in. compression to about 24,000 lb. per sq. in. tension. Herein lies an important advantage of the ductile pipe. The ductile pipe will on overstressing allow yielding so that the pipe cross-section will more nearly approximate the circular form with consequent decrease in ellipticity of the cross-section, thereby producing a more uniform stress distribution. On the other hand, the brittle pipe will not allow this yielding but may allow a crack to open, with consequent failure at a much lower internal pressure than would be the case for a similar pipe of ductile material.

The writer would also like to point out the fact that the "true ultimate strength" as found by the pipe test was quite different from the "true ultimate strength" of the test pieces cut out from the pipe. By "true ultimate strength" is meant the actual stress existing in the metal at the instant of failure, i.e., the stress calculated on the actual sectional area existing at the time of fracture. Using the data on ultimate strength and reduction of area given by the author, the writer has calculated the "true ultimate strength" for the test bars cut out from the pipe. These values are given below.

| Bar location | Average true ultimate strength lb. per sq. in. |
|---|---|
| Bars cut from flanges before test........ | 115,800 |
| Bars cut from root of flanges after test... | 138,000 |
| Bars cut from mid-length of forging..... | 119,400 |

In order to get the true ultimate strength possessed by the metal of the pipe we may proceed as above, considering the pipe

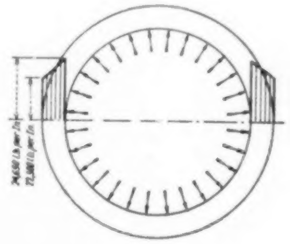

Fig. 16

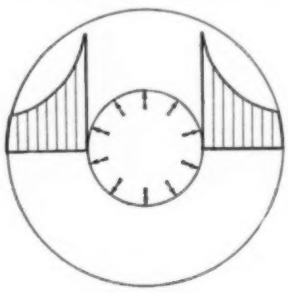

Fig. 17

a thin cylinder and taking the actual inside diameter $D'$ existing at the moment of failure. We also take the reduced thickness $t'$ found at failure. The calculated value of true ultimate strength is, then, at 5300 lb. per sq. in. pressure,

$$S = \frac{PD'}{2t'} = \frac{5300(72.56)}{2(2.812)} = 68{,}400 \text{ lb. per sq. in.}$$

By reference to the above table it may be seen that this value is only 57 per cent of the value of the true ultimate strength obtained on test bars cut from the material at the mid-length of the forging.

The discrepancy may possibly be accounted for by the fact that the loading conditions in the pipe and in the test bars cut out were somewhat different, i.e., in the test bars free lateral contraction or necking of the material was allowed, while in the pipe lateral contraction in the axial direction was prevented by the rigid fastening of the ends.

The Author. As stated by Professor Waters, in computing the ultimate strength of the pipe the author used the original dimensions to facilitate comparison between allowed and bursting stresses on the pipe as designed, just as the tensile strength of a test bar is referred to the original diameter On this basis there was an effective ratio of 62,000 ÷ 67,750 = 0.91 of the original

[6] See Appendix No. 5 of the writer's paper, "Stresses and Reactions in Expansion Pipe Bends," presented before the annual meeting of the A.S.M.E., 1927.

test-bar strength. If the stresses be calculated on the expanded dimensions it would seem that comparison should be made with the expanded physical properties. On this basis the ratio would be $67{,}600 \div 75{,}000 = 0.90$, a singularly close agreement.

Mr. Wahl has correctly illustrated the elastic stress distribution on thick and thin cylinders; but it is to be remembered that although the breech section of a gun resembles Fig. 17, the muzzle section much more nearly resembles Fig. 16. The effect of overstrain, although far less at the muzzle, is there, and to a certain moderate extent is present in the expanded pipe also. Thus a test bar taken at the inner surface of the cylinder wall at the point of fracture gave 4000 lb. greater proportional limit than was given by a corresponding bar taken at the outer surface, showing the effect of stretching the interior more than the exterior, with a consequent initial compression on relief of the pressure.

The Birnie formula was used by the author in his discussion because it applies to open-end cylinders, whereas the Lamé formula, applying to closed cylinders, gives results too low. The use of U-leathers for packing practically removed all longitudinal stress, making the Lamé formula properly inapplicable, although the divergence is not great. The two formulas differ by from about 4 per cent to 20 per cent, according to the proportion of wall thickness to interior diameter.

In view of the polite criticism given his statement that just before bursting the expanded pipe was as safe theoretically for 1840 lb. pressure as a brittle pipe for 1050 lb., the author feels that an explanation is due.

The effect of cold working on steel is to raise the proportional limit much more rapidly than the tensile strength; thus the original steel of the pipe showed 67,750 lb. tensile strength and 24,500 lb. proportional limit, whereas the cold-worked steel showed 75,000 lb. tensile strength and 50,000 lb. proportional limit—an increase in tensile strength of less than 11 per cent compared with an increase in proportional limit of 104 per cent.

Now it has been the experience of certain water-power companies that brittle pipe bursts at about, or but slightly above, its proportional limit, not developing nearly its ultimate strength—which was therefore not considered. As cold work also embrittles a ductile steel, both metals were compared on a basis of proportional limit only.

It was in view of this comparison that the statement was made. It was not put forward as a suggestion that a lower factor of safety be used in designing pipe lines, but rather to point out the actual existence in seamless forged pipe of a larger factor of safety than had been used in the calculations.

The author does not feel that it would be profitable to go into the question of the so-called "true ultimate strength" because this figure is highly variable, depending, as it does, largely upon the amount of the contraction of area.

# Physical Properties of Alloy Steels Under Various Heat Treatments and at Elevated Temperatures

By C. B. Callomon,[1] Brackenridge, Pa.

*The author confines his treatment to two of the newer and less well-known ferrous alloys: (1) so-called "stainless" iron, a steel containing from 12 to 16 per cent of chromium and less than 0.12 per cent carbon; and a "super" stainless iron containing from 12 to 20 per cent of chromium and 7 to 10 per cent of nickel. The former not only resists corrosion but is readily machinable; it is susceptible to heat treatment, under which it attains remarkable physical properties fitting it for a wide range of engineering applications. The second alloy, the strength of which is increased by hot or cold working rather than by heat treatment, resists corrosion much better than the first one, but is more difficult to form and machine. Further, it is from 7 to 15 per cent lighter than other corrosion-resisting metals and alloys. Both alloys have high tensile strength at elevated temperatures; the latter being the better in this respect, however, having an ultimate tensile strength of 25,500 lb. at 1650 deg. fahr.*

Alloys, both corrosion-resisting and heat-resisting, have been the subject of a considerable number of papers and the theme for a great deal of discussion. The attempt, therefore, to present here any new information pertaining to them may appear presumptuous. It has been the author's privilege, however, to be intimately connected with development work in connection with some of the newer and therefore less well-known ferrous alloys, and it is to these particular alloys that he wishes to confine this paper.

Two specific materials which the author has in mind are produced by the company with which he is associated under the specific trade names of Ascoloy 33 and Allegheny Metal, and are familiar not only under those two names but under many others, since each producer has coined his own designation for the material of his particular manufacture.

Most of us have followed, at least to an extent, the development and exploitation of the alloy which has come to be spoken of as "stainless steel." Its field of usefulness for the manufacture of cutlery is a well-established one. There is, however, a newer and not so well-known member of the stainless-steel family, which, to differentiate it from stainless steel, has come to be called "stainless iron."

## Stainless Iron—What It Is

Stainless iron is a low-carbon stainless steel developed as the result of efforts to produce a stainless steel which would be more workable than the cutlery grade and which would have equal corrosion resistance. As the result of these efforts, there was produced some five years ago an alloy of chromium and iron which when manufactured with low carbon content had just those qualities. As produced under the trade name Ascoloy 33 it contains from 12 to 16 per cent chromium and less than 0.12 carbon, and so-called "stainless iron" is of identical composition. It might be remarked here that the word "stainless" as applied to these chromium-iron alloys is a misnomer; they are not stainless except as compared with some other material.

[1] Manager, Alloy Steel Department, Allegheny Steel Company.

Presented at a meeting of the Philadelphia Section of the A.S.M.E. Philadelphia, Pa., January 24, 1928.

Ascoloy 33, in common with all other stainless irons, will show, under certain conditions, evidence of surface corrosion. The fact that the corrosion occurring under these conditions is a surface one and not a progressive corrosion, is the reason the alloy has such a wide field of utility as a corrosion resistant. Being of the low-carbon grade of chromium-iron alloys, it resists this corrosion in the annealed condition as well as in the heat-treated condition, and in the unpolished state as well as when polished. It is absolutely essential, however, that the surface be free from scale, otherwise corrosion will occur at the boundaries of the scale pits. Stainless steel must be both hardened and polished to become stainless, so that it can be said that the difference between stainless steel and stainless iron is a difference based entirely on carbon content. The low carbon obviates the necessity for hardening and polishing. Why this is so is readily explainable, but need not be gone into here.

Ascoloy 33 is ductile and malleable. It is readily machinable and can be formed and drawn. It may be welded, soldered, and brazed. It is procurable in all commercial forms except structural shapes.

## Stainless Iron as an Engineering Material

The fact that this particular composition of chromium and iron has received the designation "stainless iron" has caused many to overlook the fact that it is something more than a corrosion-resisting metal. In reality it possesses remarkable physical properties which make it also an excellent engineering material. In its annealed state its typical physical properties are as follows:

| | |
|---|---|
| Ultimate tensile strength, lb. per sq. in... | 72,000–85,000 |
| Elastic limit, lb. per sq. in. | 40,000–50,000 |
| Elongation in 2 in., per cent | 32–37 |
| Reduction of area, per cent | 70–78 |
| Brinell number | 140–170 |

Despite the low carbon content it may be heat-treated to show maximum physical properties as follows:

| | |
|---|---|
| Ultimate tensile strength, lb. per sq. in. | 178,000 |
| Elastic limit, lb. per sq. in. | 161,000 |
| Elongation in 2 in., per cent | 15 |
| Reduction of area, per cent | 51 |
| Brinell number | 360–370 |

In this fully hardened condition the metal is not machinable. Our best recommendation for physical properties that will best meet engineering requirements is the following:

| | |
|---|---|
| Ultimate tensile strength, lb. per sq. in.. | 110,000–120,000 |
| Elastic limit, lb. per sq. in. | 90,000–100,000 |
| Elongation in 2 in., per cent | 23 |
| Reduction of area, per cent | 69 |
| Brinell number | 225 |

Attention is called to the exceedingly high elongation and reduction combined with such relatively high ultimate tensile strength.

For any definite heat treatment the physical properties can be predicted probably with greater accuracy than is the case with any other alloy. An additional characteristic of this material that makes it particularly suited for certain engineering applications is its high tensile strength at elevated temperatures.

For example, at 1000 deg. fahr. the ultimate tensile strength is 30,000 lb. per sq. in., at 1400 deg. this figure is 11,500 lb.; at 1800 deg., 7700 lb., and at 2000 deg., 4000 lb. Accompanying these high physical values at elevated temperatures is a marked resistance to scaling at temperatures not in excess of 1500 deg. fahr.

Ascoloy 33 is an air-hardening alloy and if worked at temperatures above its upper critical point, 1500 deg. fahr., it must be annealed before subsequent machining operations can be performed. It will be seen, therefore, that if the material is hot-worked by either rolling, forging, or pressing operations, an anneal or draw is essential for subsequent machining. This annealing may be accomplished by heating slightly above the upper critical point and cooling very slowly—not in excess of 50 deg. per hour. A full anneal, however, is not essential or desirable for best machining qualities, and the treatment recommended is a semi-anneal, or to be more accurate, a draw, at a temperature of from 1400 to 1450 deg. fahr., followed by an air quench, after which machining can be done readily.

### Uses to Which Stainless Iron Is Specially Adapted

The combination of corrosion resistance, workability, and high physical values gives the metal a general utility in industry perhaps not comprehended by those not perfectly familiar with its many applications. Therefore some of the most likely uses are listed here:

- Turbine blading
- Pump rods
- Pump impellers and casings
- Pipe and tubing, for surface or subsoil service
- Valve trim for valves handling corrosive liquids, oil, etc.
- Tie rods
- Bolts and nuts
- Tank plates
- Rivets
- Condenser tubes
- Superheater tubes
- Valve parts on ammonia pumps, caustic pumps, etc.
- Nitric acid manufacturing and storage equipment.

As a matter of fact, Ascoloy 33 is indicated for all applications where excessive corrosion is objectionable but where surface beauty is not essential.

### Super Stainless Iron

Several years ago there was developed in Germany, and at about the same time in England, a modified stainless iron, or rather, a super stainless iron. It was called by the Krupps in Germany, who first made it, V-2A Steel, and by the English makers, Stabrite. The latter designation is perhaps as descriptive a word for the alloy as could be coined. In this country, the first commercial producer of the alloy under the Strauss patents was the company with which the author is connected. By them it has been developed to a degree far beyond anything that has been done with it abroad.

Allegheny Metal, as this product is designated, is an alloy of chromium, nickel, and iron, containing from 17 to 20 per cent chromium and from 7 to 10 per cent nickel. Carbon, manganese, silicon, etc., are of course present, but only as technical impurities.

For many years, nickel-chromium alloys of the type of Nichrome have been in common use. Their range of usefulness has been well established. In the developmental work connected with the making of V-2A and Stabrite, however, a new series of alloys was studied in the chromium-nickel series. Generally speaking, the nickel-chromium alloys or those in which the nickel predominates are heat-resisting, while the chromium-nickel are primarily corrosion-resisting, this being especially true of the composition under consideration. It might be added that there are also heat-resisting alloys in the chromium-nickel series, obtained by increasing the chromium content to 22 per cent or more while keeping the nickel content at from 8 to 10 per cent.

The alloy in question is a super corrosion-resisting material and is believed to be the most highly developed metal for controlling corrosion that is available commercially. It is specifically recommended for applications where surface beauty and permanence of surface are essential. Containing no copper, it cannot corrode with the formation of the well-known verdigris. Its use is recommended where a metal of the strength of steel is required but where stainless iron cannot be used on account of its susceptibility to surface corrosion.

Allegheny Metal is an austenitic steel and therefore not susceptible to heat treatment. In its annealed condition it is non-magnetic to an extent never before obtainable with a ferrous alloy. It is ductile and malleable and therefore capable of being formed, stamped, and drawn. During cold-working operations the metal hardens, and in the woik-hardened condition it is magnetic. Annealing, however, at a sufficiently high temperature causes the reversion of the metal to its non-magnetic state. It is readily weldable, using welding sticks of the same composition as the metal to be welded, and the welds when made properly are ductile and malleable. It does not machine as readily as carbon steel or as Ascoloy 33, but compares in that respect with the well-known 30 per cent nickel steels.

### Physical Properties Imparted by Working Rather than by Heat Treatment

The fact that Allegheny Metal cannot be heat-treated to impart definite physical properties does not preclude obtaining any physical properties within the possible range. They must be imparted, however, through cold or hot working rather than through heat treatment. To illustrate this point, a typical example is given. In the annealed condition the alloy has an ultimate tensile strength of 90,000 lb. per sq. in. with a yield point of 45,000 lb. per sq. in., a true elastic limit of 30,000 lb. per sq. in., an elongation in 2 in. of 61 per cent, and a reduction of area of 75 per cent. When working specifically to produce the material for engineering applications the ultimate tensile strength should be 120,000 lb. with a yield point of 86,000 lb., a proportional limit or true elastic limit of 68,000 lb., together with an elongation in 2 in. of 36 per cent and a reduction of area of 52 per cent. It should be borne in mind, however, that the alloy is no more resistant to corrosion in its work-hardened condition than when annealed. As a matter of fact, it is very doubtful if the corrosion resistance of the annealed material is not superior to that of the work-hardened material.

In the drawing of Allegheny Metal, considerably more press power is necessary than in the drawing of similar shapes from steel, due entirely to the work hardening of the material. Therefore, more frequent annealings will be necessary. For example, a sample 0.078 in. thick showed a tensile strength in the annealed condition of 88,000 lb. per sq. in., with a yield point of 42,000 lb. and an elongation in 2 in. of 68 per cent. When this same sample was cold-rolled to 0.049 in. thick the tensile strength had been increased to 158,000 lb. with a yield point of 153,000 lb. and an elongation in 2 in. of 18 per cent. These figures make obvious the reason for frequent annealings in the cold working of the material.

Regarding annealing, it might be mentioned that the material begins to soften at temperatures from 1500 deg. fahr. The higher the annealing temperature is above 1500 deg., the softer the material becomes, provided the maximum annealing tem-

perature does not exceed 2200 deg. It has been found that material which has been work-hardened to the extent that it has become strongly magnetic can only be brought back to the non-magnetic condition by an annealing temperature in excess of 1800 deg. With this particular material the softness is a direct function of the annealing temperature.

### Properties at High Temperatures

In common with other corrosion-resisting metals, the alloy has rather remarkable physical properties at elevated temperatures, as is evidenced by the fact that at 1650 deg. fahr. an ultimate tensile strength of 25,500 lb. is obtainable, while at 1832 deg. it is 16,900 lb. and at 2012 deg. decreases to 11,300 lb. It will be seen, therefore, that Allegheny Metal has considerably more tensile strength at elevated temperatures than has Ascoloy 33. It is not recommended, however, for use at temperatures in excess of 1700 deg.

The material has an advantage over other corrosion-resisting materials in the matter of weight. In sheet form, for example, it is from 12 to 15 per cent lighter than monel metal, 7 per cent lighter than Tobin bronze, 11 per cent lighter than nickel-silver, 15 per cent lighter than copper, and 12 per cent lighter than nickel. From the standpoint of surface area, therefore, there is a considerable saving in weight to be effected through the use of this material.

The fact that it is a material of stable surface under normal corrosive influences, makes possible the use of the metal for applications involving contact with food products. It is an approved material for use in the dairy industry and imparts no taste or flavor to dairy products, nor is it attacked by these dairy products.

# The Use of Pulverized Coal in Basic Open-Hearth Furnaces

By E. L. HERNDON,[1] POTTSVILLE, PA.

*The experience of The Eastern Steel Company with pulverized coal as fuel for basic open-hearth furnaces was anything but voluntary. The company had been very happily using oil which was low in price and high in quality, when the cost of this fuel began to rise and continued until it was necessary to cease using it. Since then, for thirteen years the company has continuously wrestled with the problems arising in the development of a little-known fuel. At times it has been more than willing to abandon the entire plan. Very little working knowledge was gained before the war period, and during the war costs were of less consequence than ordinarily. After that period passed, however willing the company was to alter the design of its furnaces and change the fuel, the necessary capital was never available. After many tribulations and at times successive disappointments, some understanding of the subject has been reached, and it is believed that pulverized coal is the best fuel for conditions as they exist. It is not recommended on that account, however, that others adopt pulverized coal until a thorough examination of each situation has been made.*

THE use of pulverized coal in the basic open-hearth furnaces of The Eastern Steel Company came about as the result of a continued advance in the price of fuel oil. This paper is an account of the experience of the company in dealing with a fuel of which there was no history to serve as a guide. The company has not maintained a research department and it is not intended to consider the subject from a scientific viewpoint. The work has at all times been empirical, and no exhaustive analysis of the results has so far been undertaken.

When The Eastern Steel Company began to make steel, the open-hearth department consisted of four 50-ton basic furnaces. Fuel for these was supplied by gas producers of the hand-poked type.

From 1905 until 1910 only producer gas was used, but during 1910 it was possible to make a contract for suitable fuel oil at two and one-half cents per gallon, delivered. This contract extended over two years. From its expiration until late in 1914 the cost of oil steadily advanced until it became prohibitive. During the period last mentioned, two 80-ton furnaces were designed and built. The designers considered only fuel oil and gave no thought to the possibility of returning to producer gas. When, because of increasing cost, it became necessary to abandon oil, it was apparent that additional producer equipment would be necessary in order to operate the two 80-ton furnaces, and also considerable change in the design of the furnaces would have been regarded as desirable. In this situation the attention of those operating the open hearth was directed to pulverized coal. This seemed, at the time, to offer considerable inducement, as the only change in the furnaces which seemed to be necessary was to replace the checker-chamber bricks with a series of arches, and provide burner equipment. These changes and additions were made, and since that time pulverized coal, with oil for an emergency alternative, has been used. A layout of the plant is shown in Fig. 1.

The open-hearth-furnace plant consists of four 50-ton furnaces and two 80-ton furnaces. All have basic bottoms, all are stationary, and all are of the ordinary design which was approved at the time they were built, and very few changes have been necessary.

When the pulverized coal was first used in the furnace, it was found that the checkers were filling up with ash. It was realized that this could not be prevented, and therefore arches were substituted for the checkers because of the greater space. The arches are placed about 18 in. apart in rows, one above the other, with about three feet between the rows.

The furnaces are reversed by two dampers, one placed in each flue between the checker chamber and the stack. This gives the products of combustion a direct path to the stack.

The slag pockets are equipped with removable structural-steel boxes which fill up in about fifteen days. The time ordinarily required to pull two boxes and get the fuel on the furnace again is about five hours.

The boxes used for the 50-ton furnaces are 15 ft. by 10 ft. by 2 ft. 5 in. deep; for the 80-ton furnaces, the dimensions are 18 ft. by 10 ft. by 2 ft. 5 in. All four sides of these boxes are tapered, and the boxes are lined with a 9-in. lining of old bricks laid up in common clay.

Each furnace is supplied with two storage bins for pulverized coal which have capacity sufficient to operate a 50-ton furnace for eighteen hours and an 80-ton furnace for fifteen hours.

The coal is supplied to the furnace from the bins by compressed-air siphons. On the 50-ton furnaces the air jet is $^3/_8$ in. in diameter and on the 80-ton furnaces, $^9/_{16}$ in. in diameter. The air pressure used is 80 lb. per sq. in.

Each furnace is supplied with the necessary equipment for using fuel oil in case of emergency. The oil supply is stored in the usual way, in a tank of considerable capacity, and is at all times on tap.

The plant for pulverizing the coal is situated near the end of the open-hearth building. See Fig. 1.

Preparation of the coal consists of crushing, drying, and grinding. At various times lump and run-of-mine have been used, and just now slack is being used.

The equipment consists of three Raymond five-roller mills and one Raymond four-roller mill. Each mill is connected to a motor. There are in addition two Cummer driers and one Jeffrey single-roll coal crusher.

When the coal is received, the railroad car is placed over a pit and the load dumped into the pit. From this it is hoisted to the top of the building, a height of about one hundred feet, by an Otis automatic dump-bucket elevator. There are two buckets, which are operated in the manner of the usual blast-furnace skip.

When it reaches the top of the skip, the coal is dumped into a storage bin which has a capacity of about two carloads; thence it passes to the crusher, located directly below the bin. When it has been crushed, it is dropped into another bin for storage before sending it to the driers.

The compartments for storing dried coal are quite small because it is thought unsafe to keep any considerable quantity of dried coal in storage. Each storage compartment is situated directly over one of the pulverizing mills, and the height of the

[1] Receiver, The Eastern Steel Co.

Contributed by the Iron and Steel Division and presented at the Spring Meeting, Pittsburgh, Pa., May 14 to 17, 1928, of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.

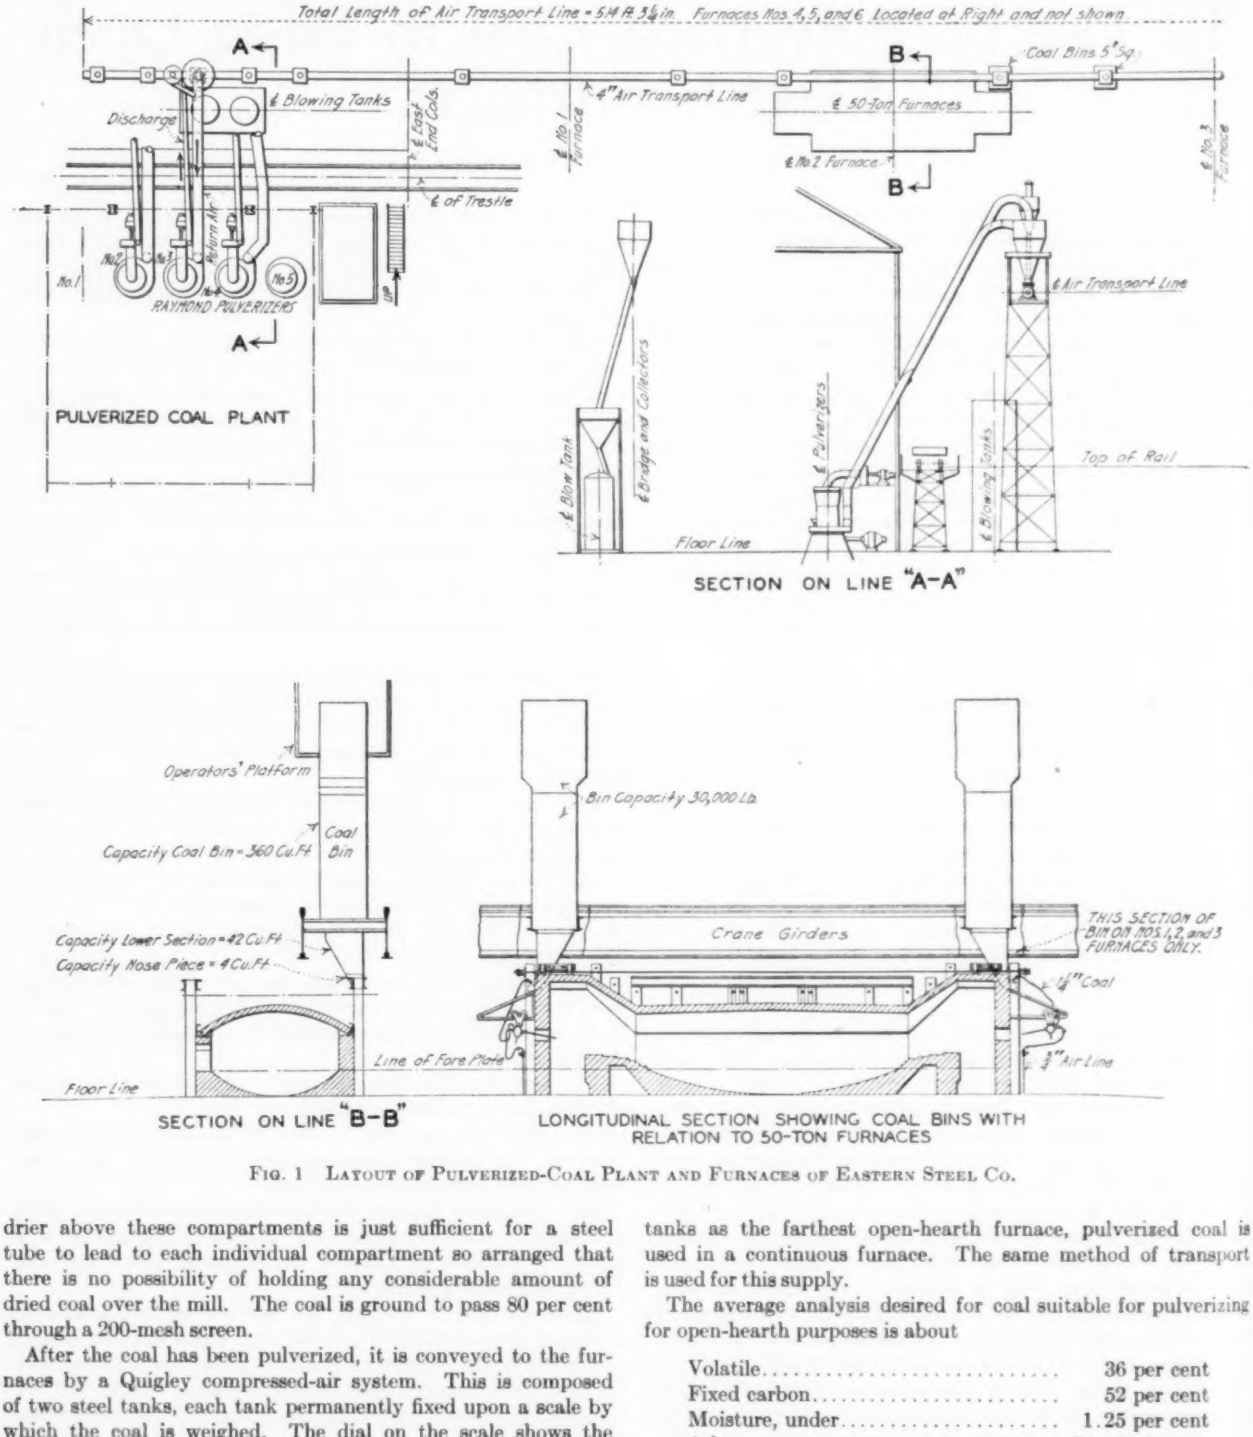

Fig. 1 Layout of Pulverized-Coal Plant and Furnaces of Eastern Steel Co.

drier above these compartments is just sufficient for a steel tube to lead to each individual compartment so arranged that there is no possibility of holding any considerable amount of dried coal over the mill. The coal is ground to pass 80 per cent through a 200-mesh screen.

After the coal has been pulverized, it is conveyed to the furnaces by a Quigley compressed-air system. This is composed of two steel tanks, each tank permanently fixed upon a scale by which the coal is weighed. The dial on the scale shows the amount of coal in the tank when it is being filled, and also shows the amount when the coal is being discharged, so that the readings show the weight of the amount taken to the furnaces. Compressed air is used for transporting the pulverized coal through a 4-in. pipe which connects the tanks just mentioned with the coal boxes over the furnaces. The distance from these tanks to the box at the farthest furnace is 450 ft. Each furnace supply box is furnished with a valve so that any box may be refilled as needed.

At a 12-in. mill located at about the same distance from the tanks as the farthest open-hearth furnace, pulverized coal is used in a continuous furnace. The same method of transport is used for this supply.

The average analysis desired for coal suitable for pulverizing for open-hearth purposes is about

| | |
|---|---|
| Volatile | 36 per cent |
| Fixed carbon | 52 per cent |
| Moisture, under | 1.25 per cent |
| Ash | 6 to 8 per cent |
| Sulphur under | 1.25 per cent |

The operation of the open-hearth furnaces does not now present more difficulty than with producer gas, though it is not as simple as with oil. All-cold charge is used, and the time for charging is about four hours. The scrap here is, in general, quite light and the percentage of pig is kept as low as possible because of cost; one heat in twelve hours is considered as 100 per cent, and it is usually possible to keep fairly near this through the campaign. The life of furnaces is about 200 heats for one roof. Usually a

second roof can be put on without disturbing any other part of the furnace, and then an additional 100 to 150 heats can be obtained with this second roof.

The coal required runs as low as 500 lb. and as high as 600 lb. per ton of ingots. The wide variation is partly due to character of coal, partly to the charge, to the analysis required in the product, and a little to the age of the furnace, although the time from tap to tap varies less than was formerly thought possible. The temperature maintained in the furnaces is essentially the same as that with producer gas.

There have been infrequent explosions, one in which one life was lost and considerable damage to property resulted. The others were not of consequence. The cause of the serious explosion is not known, although reasonable theories and some conjectures are held, but no proof. The experience during thirteen years does not seem to indicate extra-hazardous occupation.

Experience with pulverized coal has convinced the company that very little has been learned, certainly no more than has been included in this paper. Comment and criticism from those who are interested are invited. If engineers interested in the subject care to visit the plant, they will be welcomed.

## Discussion

C. D. Northam.[2] After reading the very interesting paper by Mr. Herndon, detailing the experience of his company with powdered coal in firing open-hearth furnaces, the writer was curious to know just what this 500 to 600 lb. of coal per ton of ingots represented.

Taking the average analysis of coal used, it is evident that the constituents do not total 100 per cent, and it is assumed that the moisture given is "after drying," while the remainder of the analysis is "as received." Rearranged, we would have the following analysis, after correcting moisture:

| | Proximate analysis | Combustible |
|---|---|---|
| Volatile, per cent | 36.00 | 40.30 |
| Fixed carbon (and sulphur), per cent | 53.25 | 59.70 |
| Ash, per cent | 7.00 | .... |
| Moisture by difference, per cent | 3.75 | .... |
| Total, per cent | 100.00 | 100.00 |

If we calculate the ultimate analysis from the above proximate analysis, the following results are obtained:

| | |
|---|---|
| Hydrogen, per cent | 4.78 |
| Nitrogen, per cent | 1.44 |
| Carbon, per cent | 73.15 |
| Sulphur, per cent | 1.25 |
| Ash, per cent | 7.00 |
| Moisture, per cent | 3.75 |
| Oxygen, per cent | 8.63 |
| Total, per cent | 100.00 |

From this analysis, by Dulong's formula, the calorific value of the coal used is found to be:

$$h = 14{,}544\,C + 62{,}028\left(H - \frac{0}{8}\right) + 4050\,S$$

$$= 14{,}544 \times 73.15 + 62{,}028\left(0.0478 - \frac{0.0863}{(8)}\right) + 4050 \times 0.0125$$

$$= 12{,}985 \text{ B.t.u. per lb. of coal as received.}$$

Correcting for the maximum allowable moisture in coal as fired, the calculated heat value of coal used is:

[2] Mechanical Engineer, Chicago, Ill. Jun. A.S.M.E

$$\frac{12985}{0.975} = 13{,}318 \text{ B.t.u. per lb. of coal as fired.}$$

Using this result, it is evident that the heat rate per ton of ingots, using powdered coal as fuel, in a basic open-hearth furnace varies from

$$500 \times 13{,}318 = 6{,}659{,}000 \text{ B.t.u. per ton}$$

to

$$600 \times 13{,}318 = 7{,}990{,}800 \text{ B.t.u. per ton}$$

or an average of 7,324,900 B.t.u. per ton of ingots. As this is several million B.t.u. higher than good average practice using oil as fuel, the question arises, "Where do these extra heat units go?" The writer believes an analysis of existing stack and regenerated air temperatures would show this; at least, it would be interesting to know what temperatures are obtained using these arch-work generators.

E. W. Wagenseil.[3] Regarding the application of powdered coal to open hearths, the writer would ask if the author has any data available as to air temperatures at the top of the checkers—of the air that was preheated; and also what percentage of the total air was preheated and what percentage entered as old air around the burner. Also, if temperatures were taken of the heated air, were they taken with an aspiration pyrometer or with just an ordinary thermocouple? Finally, what percentage of oxygen was found in the flue gas?

It would seem apparent that with arches substituted for the checker bricks, the air temperature could not have been very high. In that case a modern air preheater heating the air to, say, 1000 deg. fahr. before the air entered the checker chambers might result in a marked reduction in fuel required per ton of steel made.

I. A. Nicholas.[4] The Clairton plant of the Carnegie Steel Company has had about three years' experience in the use of powdered coal in open-hearth furnaces. The reason for using it was a shortage of natural gas; therefore it was a temporary proposition, and as soon as the coke-oven plant was installed, the furnaces were changed over to coke-oven gas instead of returning to natural gas.

It has been ten years since the powdered coal was used, and the writer's memory is not very distinct on all phases of the experience with it. However, it is recalled that the fuel consumption was 500 to 600 lb. per ton of steel and the life of the roofs was about 200 heats.

G. E. Heine.[5] A very important question in connection with the application of powdered coal to take the place of fuel oil for reheating furnaces of the regenerative type is that of ash disposal. A unit pulverizer operated very successfully in a certain plant for the first few days. Then, although the checker chamber were cleared of all checker brick, they still continued to fill up with ash. It was found that this ash, under the action of the hammer or the press, became imbedded in the surface of the steel.

A few rough operating calculations produced results that may prove interesting. They showed that for one dollar with powdered coal, unit pulverizer system, including the cost of the current, 1407 lb. of steel was heated, whereas with fuel oil it was only 558 lb. It would seem that there should be an opportunity to make a saving from the fuel standpoint but for the ash.

It would be of great interest to the writer to have a word from

[4] Fuel Engineer, Carnegie Steel Co., Clairton, Pa.

[5] Power Engineer, Erie Forge & Steel Co., Erie, Pa. Mem. A.S.M.E.

some one who has met this problem of the handling of the ash and the effect of the ash on the steel.

W. P. Chandler.[6] Attempts have been made in firing open-hearth furnaces with pulverized coal to grind the coal particularly fine, the idea being that the resultant ash would be fine enough to be carried out of the furnace and through the flues by the velocity of the exit gases. In order not to interfere with this action, the checkers were removed. However, a continual building up has taken place in the chambers, and the loss of preheat in the air caused by the removal of the checkers has been reflected in the fuel consumption of the furnace.

The figures of 500 to 600 lb. per ton of ingots as given by Mr. Nicholas are common.

H. W. Brooks.[7] This matter is in a research stage. It may serve a useful purpose; we do not know. We want a contribution of experience so that the things which were foolishly done ten years ago will not be repeated, and it is the writer's belief that the experience which has been developed at Pottsville and the experience developed by the Atlantic Steel, plus the experience of Homestead and Clairton, if properly correlated, would form a nucleus for some useful developmental work along this line.

None of us think we have the answer—we haven't. We do not know whether what we have is worth while or will prove to be the proper thing or not, but attention is called to the figures given by Mr. Heine, showing operating economies in the relation 558 to 1407. Are we going to say it cannot be done because it never has been done, or will we take a research attitude of mind and see what we can do? Shall we go as far as we can and see how far we can go?

That is all we are trying to do in this whole situation, and it is only with the helpful cooperation of all interested in the problem that the ultimate result to be desired will be brought about.

# Recent Developments in the Use of Nickel Steels

By CHARLES McKNIGHT,[1] NEW YORK, N. Y.

*After recounting the early uses of nickel steel for armor plate, guns, and projectiles, the author deals at some length with the development of its use in locomotive construction for heavy forgings and later for the shell plates of high-pressure locomotive boilers. He then touches briefly on three recently developed iron-nickel alloys—Invar, Permalloy, and Nickeloy—the latter two being employed extensively in electrical work, and with the substitution of nickel-chrome-steel castings for those of manganese steel in trackwork. He concludes with a statement of the advantageous properties conferred on cast iron by the addition of nickel.*

IT IS THE scope of this paper to cover very briefly uses for nickel steels (and other nickel-iron alloys) which for their size, manner of treatment, or properties are new or unusual. There is already complete and adequate information on the manufacture, heat treatment, and use of these steels as ordinarily employed, but it might be of value to sketch the history of nickel steel and define its position today.

The origin of nickel steel lies back beyond history, because all meteors are essentially nickel steel, but the first recorded use was in the Middle Ages when some of the famous Damascus swords are known to have contained nickel. In 1821, after a gap of centuries, Faraday, searching for a better material for mirrors, investigated the properties of "meteoric irons." In 1885 the commercial manufacture of nickel steel was begun in France, and in 1889 Riley read his paper on this subject before the Iron and Steel Institute.

## Early Uses of Nickel Steel

This began the real growth. Creusot in France made some $3^1/_2$ per cent nickel-steel armor plate, which demonstrated its superiority so conclusively that in 1890 the United States Navy adopted it for armor after a conclusive and competitive test. Authorities state that the adoption of nickel steel for armor plate was as revolutionary as the construction some twenty years later of the "Dreadnought."

By 1896 nickel steel was being quite widely used—in naval vessels, for guns, armor plate, and projectiles, in heavy machinery, to a limited extent on the railroads, and quite largely for bicycles. The development of the automobile helped the growth, and from 1900 on till after the war the production curve mounted steadily.

It may be truthfully said that nickel steel is not only the oldest alloy steel but the most used. An idea of its widespread employment today can be gained from the fact that every automobile uses some nickel steel—the amount running from 1500 lb. per car down to a few pounds. This preponderance toward nickel steels is in great part due to two characteristics that are almost unique among alloying materials: nickel alloys with iron in all proportions, and there is no loss of the alloy during melting. The latter fact renders its manufacture more exact as well as more economical initially, because less alloying material is used and eventually because the nickel in scrap can be fully recovered on remelting. Nickel, once purchased, is never lost.

## Nickel Steel in Locomotive Construction

One of the first uses for which nickel steel was employed was in locomotive construction, and yet until recently the development has lagged. It is generally admitted that there is no greater field for alloy steel at the present time than the railroads, which use very little in proportion to the total tonnage of steel employed. The reason for this is, of course, that in the first place the railroad shops have not, for good reasons, kept pace with the automotive industry in being equipped and educated to handle and heat-treat alloy steels, and, second, because about fifteen or twenty years ago, following the success of the alloy steels in the automobile, the railroads were induced to adopt similar steels for their purposes. It is manifestly ridiculous to compare the rear-axle shaft of an automobile to the massive driving axle or main rod of a locomotive, but the mistake was made of recommending the same steels treated in a similar way. So many failures ensued that for years the railroads were unwilling to consider the use of anything which might be considered an alloy steel, but beginning about 1915 and increasing each year they began to use frames and forgings which were alloy steels in the sense that they carried a percentage of alloying elements, but were not alloy steels in the sense that they were not intended to be heat-treated other than by normalizing or annealing.

In the development of locomotive parts the tendency has been to higher and higher tensile strengths. Taking locomotive driving axles for example, wrought iron was originally used with an ultimate tensile strength of about 45,000 lb. per sq. in. This was later replaced by carbon steel with an ultimate tensile strength of 75,000 lb. per sq. in., and carbon steel in turn has quite generally given away to alloy steel with a tensile strength of 90,000 lb. per sq. in. or higher. It has perhaps been natural to reason that if failures occur with one material a stronger material will obviate the difficulty, and it has been this reasoning which has induced the railroads to use steels of higher and higher strengths.

The logic of this reasoning can be questioned, and it seems that too much attention has been paid to strength and not enough to other characteristics, such as the reduction of area, elongation, impact, and fatigue values. The practical limit of strength, however, has now been reached for normalized forgings, and as it seems to make no difference what alloy is used, it is not possible greatly to increase the strength over that now being reached. As the strength of the steels employed has been progressively raised, so has the carbon content. Wrought iron, of course, contains comparatively little carbon; the steels in use today run in the neighborhood of 0.45–0.50 per cent carbon.

In the present dilemma recourse has been had to the other extreme, and comparatively low-carbon (0.15–0.30) nickel steel has recently been used and is being favorably considered as a material for the stressed forgings on locomotives. Such a material will show an elastic limit of 55,000–60,000 lb., an ultimate tensile strength of 70,000–90,000 lb., with unusually good elongation and reduction of area—about 26–35 per cent and 50–70 per cent, respectively. These data compare with those specified for the usual alloy-steel forgings of 60,000 lb. elastic limit, 90,000 lb. ultimate tensile strength, 20–25 per cent elongation, and 40–50 per cent reduction of area, so that with a slight reduction in strength the toughness factors have been increased

[1] Development and Research Department, The International Nickel Company.

Presented at a meeting of the Philadelphia Section of the A.S.M.E., January 24, 1928.

about 25–30 per cent. It is interesting to note that the impact value for very low-carbon 3.5 per cent nickel steel is approximately 50-lb. Izod against the average of about 18–20 for normalized alloy-steel forgings of high carbon (0.40–0.50) content, and the fatigue limit is about 50,000 lb. per sq. in., which is relatively much higher than for steels now used.

## Nickel Steels Important in Railroad Use for Forging Work

These nickel steels may be of several analyses, the choice depending on economical considerations and what properties are desired. The three which are most important in railroad use

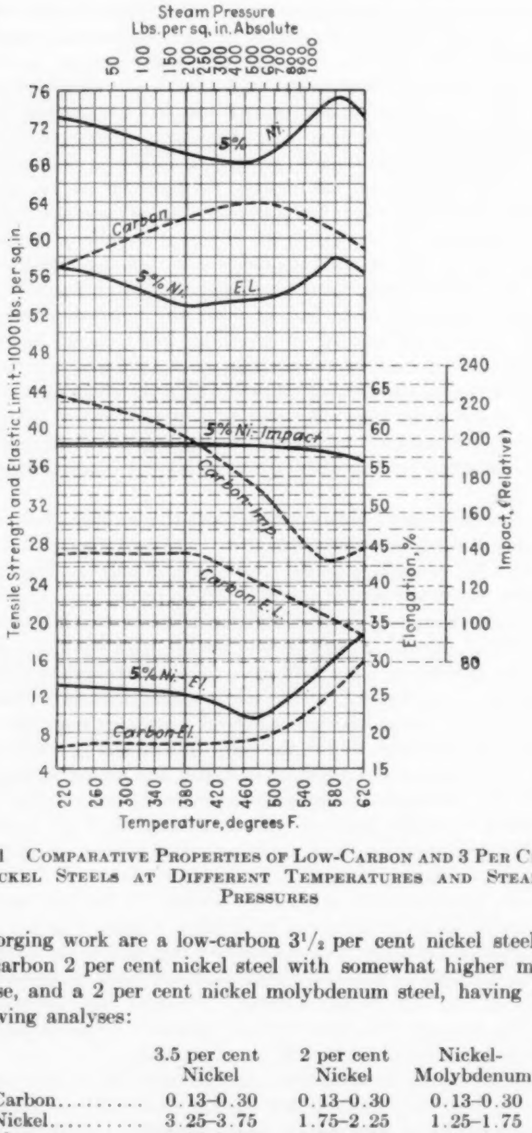

Fig. 1 Comparative Properties of Low-Carbon and 3 Per Cent Nickel Steels at Different Temperatures and Steam Pressures

for forging work are a low-carbon $3^1/_2$ per cent nickel steel, a low-carbon 2 per cent nickel steel with somewhat higher manganese, and a 2 per cent nickel molybdenum steel, having the following analyses:

| | 3.5 per cent Nickel | 2 per cent Nickel | Nickel-Molybdenum |
|---|---|---|---|
| Carbon | 0.13–0.30 | 0.13–0.30 | 0.13–0.30 |
| Nickel | 3.25–3.75 | 1.75–2.25 | 1.25–1.75 |
| Manganese | 0.60–0.90 | 0.90–1.25 | 0.60–0.90 |
| Silicon | 0.15–0.25 | 0.15–0.25 | 0.15–0.25 |
| Phosphorus | Max. 0.05 | Max. 0.05 | Max. 0.05 |
| Sulphur | Max. 0.05 | Max. 0.05 | Max. 0.05 |
| Molybdenum | ....... | ....... | 0.15–0.25 |

All of these steels are commercial and each has its reason for use. The 3.5 per cent nickel steel shows rather remarkable properties, especially as regards toughness and impact resistance when used in the lower carbons; the nickel-molybdenum owes its slightly higher tensile results for a given carbon to the addition of molybdenum, although this makes the steel a little more difficult properly to heat-treat; the 2.0 per cent nickel steel has the advantage of being cheaper, yet with very good properties, and is the most used of the three today.

Low-carbon nickel steel is peculiarly suited for axles and pins. It appears that no matter how careful the operation of a railroad or how much warning is given to the engineman, journals and pins will occasionally run hot, and it is not uncommon for them to be cooled with water from the tender—in fact it may be noticed that quite a large number of locomotives are equipped with pipes running to the journals. Such a practice involves real punishment for any steel, and it is not difficult to understand the large number of axle failures which result from it, especially when it is realized that quite frequently the axles are allowed to get red enough to be seen in daylight (about 1200 deg. fahr.) before they are quenched by putting cold water on them. It is not reasonable to ask any steel to stand up under this treatment, but the low-carbon nickel steel has shown better results than any other and does not crack or heat-check to anything like the extent that other steels do.

While the steels mentioned have been treated with particular regard for their employment in locomotives, it should be observed that they are equally suitable in machinery of any sort where forgings of such size as to preclude heat treatment are necessary. Such uses are large shafts, connecting rods, turbine rotors, gears, etc.

The development of forging steels for locomotives has been duplicated in regard to frames. They were originally wrought iron and were then replaced by steel castings and the steel castings replaced by alloy-steel castings—always in search for higher strengths. Railroad operators state that any frame seems to be good for five to seven years, after which failures start. Occasionally when a frame fails it does so in as many as 15 places at one time, all showing true fatigue conditions. In spite of this, the tensile requirements have been raised so that the foundries are now working to a specification of 50,000 lb. elastic limit, 80,000 lb. ultimate tensile strength, 20 per cent elongation, and 40 per cent reduction of area, which characteristics are, by the way, higher than those of the regular specifications of the American Society for Testing Materials for carbon-steel forgings.

When nickel steel was adopted for locomotive frames, the present specifications were easily met with steel containing 3 per cent nickel and 0.35 per cent carbon, but it was soon realized that all advantages seemed to lie in the other direction. Obtaining permission from the railroad, the foundry was instructed to lower the carbon gradually, and it was eventually found feasible to produce with only 0.18 per cent carbon and 2 per cent nickel a frame casting showing (as an example of an actual frame) an elastic limit of 51,350 lb., an ultimate tensile strength of 83,850 lb., an elongation of 30.5 per cent, and a reduction of area of 55.9 per cent. Coupled with these data are an impact value as high as is obtainable even from a forging of the type generally used today, and a fatigue limit very nearly as high. Compared with a good carbon-steel frame casting, the fatigue limit for a nickel-steel frame is 45,000 against 32,000 lb. per sq. in., an increase of 41 per cent, and the impact value is 18.3 against 5 ft-lb., an increase of 366 per cent. It should be realized when these frames are considered that they are no small castings for a jobbing foundry, as the finished weight of a pair of frames for a locomotive is approximately 22,000 lb. and the total casting weight about 38,000 lb.

The conclusion drawn from this work on large nickel-steel forgings and castings is that nickel steel heat-treated by normalizing or annealing seems definitely to be better the lower the carbon, all things considered. The strength stays well up, while the factors indicative of toughness and resistance to impact

and fatigue are much better. It is doubtful whether this can be said of steels using alloys which confer their benefits through the formation of carbides.

### Nickel Steel for High-Pressure Locomotive Boilers

One of the most interesting and perhaps one of the most important of the newer developments is the use of nickel steel for steam boilers. For the past quarter of a century the improvements in locomotives have been along the lines of accessories which will make the operation more efficient. Such accessories are the superheater, the feedwater heater, the stoker, etc. During this period of time the steam pressure of the boilers has remained fairly constant at 150 to 200 lb. per sq. in. Recently, however, attention has been focused on this feature of pressure because the locomotive has reached a fairly high stage of development as well as because of the relatively greater efficiency which is obtained with the higher steam pressures. Perhaps no trend in the railroad field has been so definite recently as that toward higher boiler pressure, and today we have in this country several locomotives such as the *Horatio Allen* on the D. & H. which operate at a boiler pressure of 350 lb. per sq. in., and there are either planned or in the process of building some for pressures as high as 450–500 lb. Abroad the advance has been perhaps more rapid than in this country, and there are in use today locomotives with boiler pressures as high as 1100 lb. per sq. in.

The trend toward higher steam pressure is being hastened on account of the limitations in weight and size. Our forefathers, had they had the foresight to see the eventual development of the railways in this country, would probably have adopted in the beginning a wider gage for the tracks and would have built the fixtures along the right of way, such as bridges and tunnels, larger to accommodate the trains of the future. As it is, the railroad locomotive has very nearly reached the limit of size. It is of course out of the question to talk of increasing the gage of the tracks or rebuilding all the tunnels and other limiting structures along the right of way in order to make possible larger trains, and the bridges would have to be rebuilt and the right of way materially changed to carry any heavier loads.

Recently one of the important railroads on this continent, in designing new locomotives for both passenger and freight service, was faced by the conflicting demands for more power with no increase in weight. Their locomotives were already up to the limit of weight and size. The only solution, therefore, was in a higher boiler pressure with no increase in weight, which meant that the boiler would have to be constructed out of plate of the same thickness as before. After long deliberation they decided to take an unprecedented step in using a 3 per cent nickel steel in place of carbon steel for the boiler shell. It was not only an unprecedented step but a very venturesome one. True, nickel steel had been successfully used abroad for boilers, but never for railroad service or in a locomotive type of boiler. However, there were some features that made their course seem advisable. The ultimate tensile strength of the 3 per cent nickel-steel boiler plate is approximately 40 per cent higher than the ultimate tensile strength of the carbon-steel, while the elongation and reduction of area are practically the same. In other words, the nickel-steel plate was 40 per cent stronger with no diminution in toughness. This 40 per cent increase in strength made it feasible to increase the boiler pressure from the normally carried 200 lb. up to the desired pressure of 250 lb. without overstepping the limit of conservatism. As a matter of fact, it would have been possible to go as high as 275 lb. with the same or a greater factor of safety.

Equally as important as the tensile characteristic of the steel, although almost unknown, are the characteristics of carbon-steel and nickel-steel plate under actual conditions of use in a boiler. It has long been known by boiler manufacturers that static tests on material give no real indication of the suitability of boiler plates for service, and even the impact test on the plate as received is not a good guide. The reason for this is that plates which are entirely satisfactory in the raw undergo alterations during the manufacturing processes, or perhaps later while in operation, which make them brittle. The actual embrittling phenomena have been termed "aging" and "recrystallization." By the term "aging" is understood the change in the strength of the plate which takes place gradually after it has been stressed when cold beyond its elastic limit. This condition is shown by the reduction in the impact-test value as well as by the embrittlement of the material. The term "recrystallization" refers to the phenomenon which is produced through stressing the material while cold and then subjecting it to higher temperatures (such as in boiler service).

Practically, in a boiler the effects of either aging or recrystallization or both may occur because the plates are stressed during

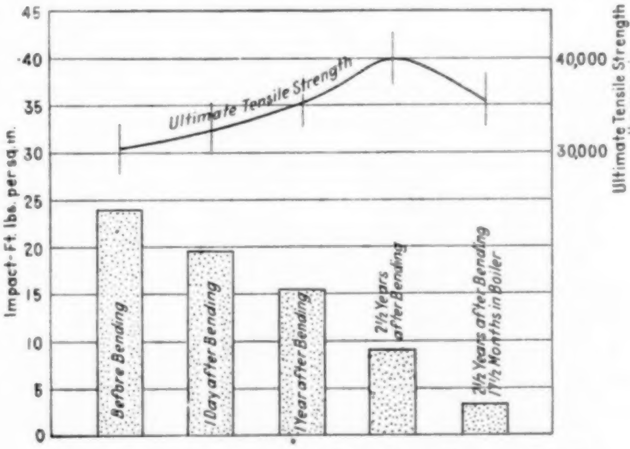

Fig. 2 Service Test of Carbon-Steel Boiler Plate
(C, 0.11; Mn, 0.53; P, 0.26; S, 0.31. Plate 0.8 in. thick by 22.5 ft. long, annealed before bending at 1685 deg. fahr.)

forming and bending in the manufacture of the boiler, or they may occur after the boiler is in commission as a result of temperature stresses which are induced by differences in the temperature at various parts of the boiler. The injurious effects will become more noticeable as the boiler pressure and consequent thickness of the plates increase because of the great difficulties of forming, bending, and riveting heavier plate, as well as because of the fact that increased heating surface and higher rates of evaporation offer more favorable conditions for temperature differences and additional stresses in the boiler.

It is here that nickel steel offers another distinct advantage over carbon steel. Fig. 4 shows the values of the impact test on carbon steel before and after aging and recrystallization, as well as those for nickel steel. It will be noted that where the carbon steel, after aging and recrystallization, shows only a small proportion of the original impact value, the nickel steel is affected only to a slight degree.

It must be remembered that the strength of a plate does not vary in direct proportion to the thickness. Therefore, to maintain the same factor of safety with higher boiler pressure using carbon-steel plate, the plate would have to be considerably thicker than indicated by the ratio of boiler pressures. This would introduce more liability to embrittlement through aging and recrystallization, because the effect is greater as the thickness increases. By the use of nickel steel it has been possible to use

higher boiler pressures with the same thickness of plate (and consequently the same boiler weight), with an actual increase in the factor of safety due to the lessened liability of embrittlement. This essentially amounts to saying that by substituting nickel steel for carbon steel the factor of safety was increased although the pressure was raised, but had the thicker carbon-steel plate been used the factor of safety actually would have been reduced considerably.

It was hard to predict before these locomotives were built just how effective they would be, although it was of course known that the theoretical drawbar pull would be increased by about 20 per cent. It was found when the locomotives were put in service that the actual drawbar pull was increased somewhere in the neighborhood of 10 per cent, and, as was expected, the factor which limited this actual drawbar pull was the adhesion of the driving wheels to the rails. In other words, had the wheels had sufficient adhesion it would have been possible to develop the full 20 per cent. The accelerating power of the locomotives was increased to a marked degree, as was the maximum speed. The superiority of the locomotives is succinctly expressed by the statement, "The new passenger locomotives will haul sixteen cars instead of fifteen cars ten miles an hour faster, and do it on the same coal used by the old locomotives."

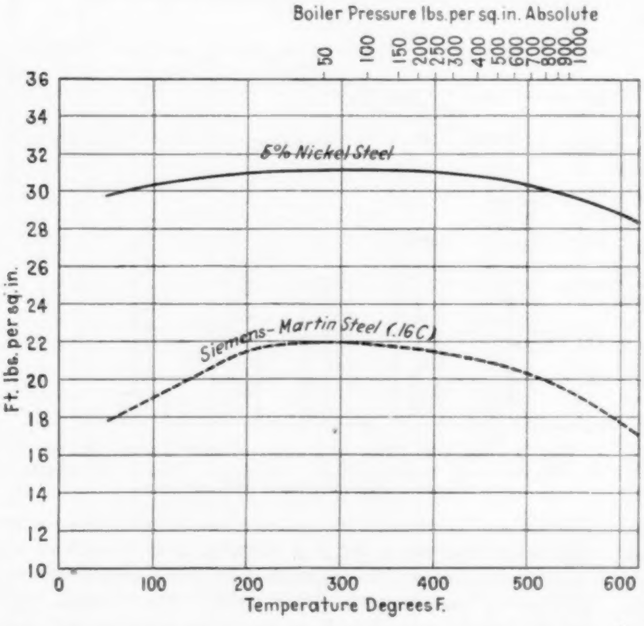

FIG. 3 IMPACT TESTS OF NICKEL- AND LOW-CARBON-STEEL BOILER PLATES AT DIFFERENT TEMPERATURES AND BOILER PRESSURES

The success of this new type of boiler is indicated by the fact that in this country two years ago there were not more than two or three nickel-steel boilers in existence or seriously contemplated, while today there are in service more than fifty nickel-steel locomotive boilers about equally divided between passenger and freight, and almost daily inquiries indicate increasing interest. This interest is not confined entirely to the locomotive field as the manufacturers of stationary boilers also appreciate the advantages of this material.

While not in any sense a consideration for the adoption of nickel steel for these boilers, a feature not to be overlooked was that of the increased resistance to corrosion of the nickel-steel boiler plate. There has always been considerable trouble, especially in bad-water districts, with firebox sheets. These sheets are exposed to the hardest service in a boiler due to the actual contact with the fire on one side and with the water on the other, together with the fact that they are perforated every few inches to carry staybolts. If the boiler feedwater is corrosive to any degree, it will start cracks around the staybolt holes, and these often develop into long cracks reaching up and down the whole side of a firebox. The use of a 3 per cent nickel-steel plate here shows markedly increased resistance to corrosion for the reason that the nickel in the steel confers a certain amount of immunity, as well as because the stresses around the staybolt holes do not affect the nickel-steel plate as severely as they do carbon steel. It is of course recognized that the corrosion cracks start where the steel has been stressed. It seems safe to say that a great deal of the trouble with these sheets will be obviated by its use, and the railroads which have adopted nickel steel for this purpose are apparently well satisfied.

For boiler tubes the situation regarding corrosion is exactly the reverse of that for shell plate as corrosion resistance is here the primary consideration and the increased strength has little to do with it. Boiler tubes running from 0.10–0.20 carbon and containing about 2 per cent nickel have shown in actual service a life of from seven to fifteen times that of carbon-steel tubes in districts where the water is bad. This of course has been sufficiently encouraging to warrant the standardization of nickel-steel boiler tubes in bad-water districts for the particular railroad quoted, and in addition there are a large number of railroads which either have nickel-steel boiler tubes under test or are using them as a regular material on some portions of their lines. Their use is not entirely new, as tubes with a higher percentage of nickel were used by several of the navies, among them our own, as long ago as 1900, and ones with a lower nickel percentage only a few years later. The unexplained peculiarity of these tubes has been the fact that boiler scale collects to a much less degree on them than on the ordinary tubes. It has been reported in at least one case where a boiler was tubed partly with carbon steel and partly with nickel steel, that the nickel-steel tubes outlived three sets of carbon-steel, and when removed were found to be in practically the same condition as when they came from the mill: that is, with the mill scale perfectly apparent.

Staybolts have customarily been made of wrought iron because they are subjected to very severe conditions of repeated bending as well as of corrosion. For several years an English concern has been substituting steel staybolts for iron ones with excellent results, and these results were attributed to the fact that the steel carried nickel. Recently in this country the steel staybolts have been encroaching very rapidly on the wrought-iron bolts, and practically all these steel bolts carry nickel, usually around 2 per cent but running down in some cases as low as 0.50 per cent.

## NOVEL EMPLOYMENT OF NICKEL-IRON ALLOYS

*Invar.* Considerable time has been spent on locomotives because they happen to include three new developments. Other forms of power are being improved by a novel employment of nickel steel, or, if it is preferred, an iron-nickel alloy. Invar, which is quite well known, consists of approximately 35 per cent nickel, the remainder essentially iron, and has been used for standards of length, measuring tapes, clock pendulums, etc., because its thermal coefficient of expansion at ordinary temperatures is practically zero (0.8 part per million per degree centigrade). Naturally, the quantity of Invar used for such purposes has been very limited, but this quantity has been increased many hundred per cent in the last two years through its use in automobile pistons and is almost worthy now of being designated as a tonnage. Aluminum (and other light alloys) for pistons in internal-combustion motors would have had a much more extended

use on account of the advantage obtained by lightening the reciprocating parts, were it not for the difference in thermal expansion between cast iron and aluminum. If the aluminum piston is made with the usual allowance for expansion, it will expand faster in use than the cast-iron cylinder and eventually bind and score the cylinder wall. On the other hand, if allowance is made in machining for this difference in expansion the piston will be too loose at low temperatures, where the automobile motor must necessarily operate frequently, and this will result in a piston slap. These difficulties are now remedied by casting into the aluminum piston two strips of Invar which hold the piston-pin bosses in place. The coefficient of expansion of the Invar being practically zero and that of aluminum about 15 parts per million per degree, it is comparatively simple so to place the right mass of Invar in order to make the average expansion of the compound piston equal to that of cast iron (about 11 parts per million). In addition, the strips of Invar prevent the scoring of the cylinder due to the piston's taking an elliptical shape from the straining action of the piston pin—a fairly common trouble.

*Permalloy.* Other high-nickel-iron alloys have, like Invar, been of more academic than industrial interest but are now increasing in use. There was discovered in the Bell Telephone Laboratories about the time of the war an alloy named "Permalloy" consisting of 78 per cent nickel, remainder iron, which, subjected to proper heat treatment, showed a magnetic permeability much higher than any known material. It was not used practically until after the war, but was then taken up by the Western Union as a material for increasing the working speed of its submarine cables. In 1922, after considerable experimentation during which the characteristics of the material were investigated at temperatures and pressures coinciding with those encountered in submarine telegraphy, 120 miles of cable were made with Permalloy sheathing and laid on the bottom of the ocean in a circle with both ends ashore at Bermuda. So satisfactory were the characteristics of this cable that the cable laid in 1924 to the Azores for connection to Italy and Spain was ordered to be sheathed with Permalloy, and this first transatlantic cable was in turn so successful that the latest cable to England laid in the past year was similarly constructed.

The cost of a cable of such length reaches so high in the millions of dollars that it is essential for economic operation to increase the speed to the maximum possible. However, on the old cables a speed of 300 words per minute was the maximum obtainable, and the majority of them cannot exceed 150 words per minute. The new cables were able to handle with ease 1500 words per minute and it is possible that they can go higher than this. The amount of Permalloy used in a transatlantic cable is both gratifyingly large and surprizingly low. The tape is wound spirally on the whole length of the cable but it is only 0.006 in. thick. Therefore, the banding in a transatlantic cable is a strip of Invar 0.006 in. × 0.125 in. × 61,000,000 ft. long. The total weight in the new transatlantic cable is only 30,800 lb., containing 24,640 lb. of nickel.

*Nickeloy.* The difficulties in manufacturing Permalloy, especially the heat treatment, have resulted in the development of another alloy containing 50 per cent nickel and known as "Nickeloy" (or "50/50"). This does not have quite as high a permeability as Permalloy, and it also is not as nearly as sensitive to heat treatment. In common with Permalloy it shows relatively a very much greater magnetic permeability at low field strength than at high. At field strengths such as those met with in communication work, both of these alloys show an enormous superiority over ordinary transformer-core materials, such as iron and silicon steel, as Permalloy is thirty times more permeable than ordinary transformer iron and its hysteresis curve covers $^1/_{16}$ of the area of that of iron. Such characteristics, coupled with the relative insensitivity of Nickeloy to heat-treating and stressing, as in punching, make it the core material par excellence for radio transformers for which it is now being more and more widely used as the demand for improved radio reception grows. The magnitude of this relatively unimportant field can be gaged by the fact that recently one concern alone was using daily 60,000 lb.—or two carloads of sheets—for radio-transformer cores.

The results obtained with this material for radio-transformer cores has caused investigation as to its suitability for power transformers. Here the field strengths are naturally much higher and at first glance it seems impossible to reconcile the permeability curve of the nickel-iron alloys with the demands of the power field. However, these alloys are now being used for one particular application—a current transformer for switchboard use—and it is not inconceivable that, by judicious designing, this material will be made available to the production and transmission of power. Obviously the present high price is a deterrent. If, however, nickel-iron alloys are used in much

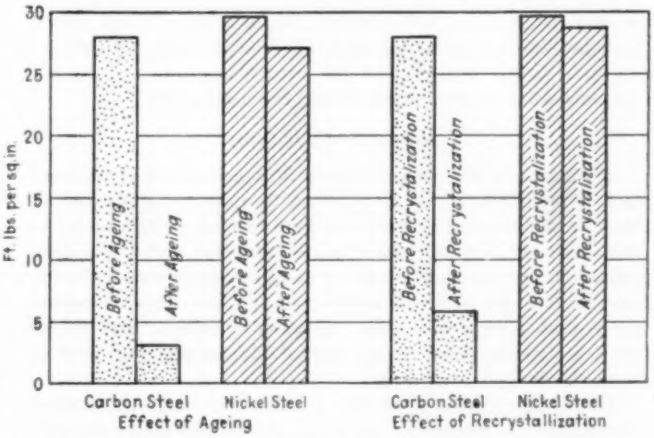

FIG. 4 AGING DATA ON LOW-CARBON AND NICKEL STEELS
(Carbon steel stressed under 36,000 lb. per sq. in. before aging; nickel steel under 61,200 lb. per sq. in. before aging.)

larger quantities the volume itself will reduce the cost. If the use of silicon steel for transformer cores in place of low-carbon steel or iron saved the power producers and consumers of this country $15,000,000 during 1925, as one authority states, there is ample incentive for the adoption of a core material that will still further reduce losses.

Ordinarily it would not seem logical to use the same materials for such opposite characteristics as maximum magnetic permeability and for non-magnetic qualities, but nickel steels are used for such things as the end plates and other parts of electrical generators, for switchgear, and for transformer components in order to avoid the induced eddy currents and other losses encountered if a magnetic material is used. The enforced installation by many of the railroads of automatic train-control apparatus opens up tremendous possibilities in this field. All existing types of train-control apparatus, as far as is known, employ a magnetic coil in a suitable housing along the right of way to influence the pick-up mechanism of the locomotive. These coils are placed every three-quarters of a mile or every mile, and there must be one for each track—which indicates the number eventually to be used. It is essential that these cases be non-magnetic, and it is desirable that the eddy-current loss be as low as possible. The nickel-iron alloys (either 18 per cent nickel—6 per cent manganese steel or high-nickel-manganese cast iron)

have an advantage over other non-magnetic materials in that the high electrical resistance exhibited reduces the eddy-current loss very materially. Hadfield's (12–14 per cent) manganese steel had a limited use, but suffered by not being forgeable or machinable.

### Nickel-Chrome-Steel Castings vs. Manganese-Steel Castings

The difficulties of handling manganese steel have always been a distinct detriment to this otherwise excellent product. In spite of this, manganese steel is very widely employed for wear-resisting castings, such as crusher and grinder parts and railroad trackwork. For the latter work it is further handicapped because manganese steel will flow under impact and because it is not weldable. Recently, therefore, a new development has arisen of replacing manganese steel for trackwork with a heat-treated nickel-chrome-steel casting. These nickel-chrome frogs, switches, and crossings wear as long or longer than manganese steel; do not flow under impact; are cheaper; and finally, when they are worn to a degree that would necessitate scrapping manganese steel, they can be built up by welding. Such castings analyze carbon 0.45–0.55, chromium 0.60–0.80, nickel 2.50–3.00, are heat-treated by a double anneal (similar to locomotive frames), and develop an average of 67,000 lb. elastic limit, 107,000 lb. ultimate tensile strength, 17 per cent elongation, and 26 per cent reduction of area with a Brinell hardness of 219.

### Nickel in Cast Iron

Often a line of investigation will be dropped because of apparent lack of results and later be followed to a successful conclusion. Back in the nineties experiments were carried on with nickel in cast iron, but results seemed to indicate that nickel was deleterious to iron, so up to a year or so ago the only uses for nickel in cast iron were in a mixture for rolls that lay in such a carbon range that it could with equal propriety be called a cast iron or steel, and as the lesser constituent of Mayari pig iron, used to some extent by foundrymen.

Finally the effects of nickel on cast iron were investigated thoroughly by laboratory methods, and it was found that the apparently bad results obtained with nickel were due to the complex nature of cast iron and the failure to recognize the effect of other elements when nickel was added.

Since these investigations the use of nickel cast iron has literally grown by leaps and bounds, and it shows promise of continued expansion.

Briefly, nickel in cast iron tends to refine the grain; to increase the machinable hardness; to increase the resistance to wear; to increase the strength; to reduce the chill; and to eliminate porosity. This list sounds like the collection of ills cured by some patent medicine, especially as some of them seem contradictory. This can be explained by saying that when nickel is to be added to cast iron the other elements must also be controlled in order to gain the desired end. Small additions—0.10 to 1.00 per cent—refine the grain of cast iron. Higher amounts—3.00 to 5.00 per cent—may coarsen the grain if the silicon is not controlled. Nickel is like silicon in that it assists in graphite formation and carbide decomposition, but there is a limit—roughly 3.00 per cent—beyond which silicon is detrimental to the iron. This is not true of nickel. Either silicon or nickel will tend to reduce chilling, but the addition of nickel causes no deterioration or loss of strength or increase in grain size.

Nickel improves the machinability of cast iron because it insures freedom from chilled areas and from hard carbide spots. By its use cast iron of 250 Brinell is as readily machined as ordinary iron at 200 Brinell. The hardening due to nickel is caused by an actual hardening of the iron matrix and not through action to increase the carbides in the iron.

The increase in the wear of castings when nickel is used is due first to this increased hardness, and secondly to the finer structure and freedom from carbide particles. Under wear conditions these hard carbide particles act as a lapping compound and increase the wear considerably.

These valuable characteristics are exhibited by the addition of nickel alone in cast iron, but other metals can be used to supplement the nickel, the most common one being chromium. The conjunction of the two is mutually advantageous. Chromium is a powerful hardener of iron, but is also very active in producing chills and carbide spots. This tendency is counteracted by nickel. The best ratio of nickel to chromium is two or three to one.

Cast iron with nickel alone or in combination with other elements is now used for a wide variety of purposes, such as automobile cylinders and pistons, differential spiders, Diesel-engine cylinders, hydraulic-press castings, valve and pipe-fitting castings, electrical-resistance grids, pipe balls, steam-cylinder bushings and piston rings, and rolls for steel-mill service.

Let us return to our starting point—alloy steel—for a moment. Roller and ball bearings are being applied more and more to heavy power machinery and to railroad equipment. The advantages gained in power saving, long life, and reliability are in many cases astonishing, and some clear-sighted people predict the practical replacement eventually of all metal bearings with these anti-friction bearings. This may be visionary.

Formerly practically all roller and ball bearings used for both races and rollers (or balls) a high-chrome steel. Now the majority of roller bearings are made of a nickel-molybdenum composition. The change was made because equally as good (or better) results can be obtained in service with the new steel, the necessary heat treatment is much simplified, and the alloys in the scrap are both recoverable. The last constitutes in itself a great saving. Only about 15 per cent of the steel made leaves the factory in the form of bearings; the other 85 per cent is returned as crop-ends or machining waste to be remelted.

Developments are constantly being made in nickel steels or nickel-iron alloys, new uses are created by new needs of industry, and the possibilities of this system, embodying as it does unusual and often contradictory characteristics, are far from exhausted. The most unexpected applications arise. For example, a certain combination of nickel and chromium with iron has a very low heat conductivity. It is now used abroad for handles on cooking utensils.

# The Manufacture of Seamless Tubes

By R. C. Stiefel[1] and George A. Pugh,[2] Youngstown, Ohio

*Two methods are today available in the manufacture of seamless tubes of 4 in. and greater diameter. These are the pilger process and the automatic or plug-mill process. The cost of installation is about the same for either process. The cost of tool equipment is much greater for the pilger process and it is claimed that the quality of the tube, particularly in the matter of service, is more uniformly reliable with the plug rolling process than with the pilger process.*

*Referring particularly to the plug rolling process the authors discuss the difficulties of operation and modern improvements aimed at obviating these difficulties. A distinction is emphasized between the part of the billet directly affected, or as the authors style it, "explored," by the mandrel, and the part which is unexplored, and the smaller the unexplored section is in relation to the full section of the solid billet, the fewer are the defects on the inside of the pierced tube. This leads to the conclusion that for the production of a given size tube, as small a solid billet as possible should be used. This is proved by a formula given for power consumption in piercing. The design of piercing mills is next considered from the same point of view and the most recent developments in the use of expanding mills are described.*

THE manufacture of seamless tubes is a branch of the steel business which lately has assumed enough importance to merit closer consideration than is possible in the little time available to the authors for this purpose. The following treatment of this subject is, therefore, based on the assumption that the reader is to some extent familiar with it, and the object is to deal only with the main difficulties encountered and with the possibility of eliminating them.

## Methods of Manufacture

The two chief methods of manufacture, besides a number of others of lesser importance, when considering the production of tubes, say, 4 inches and larger, are the pilger process and the so-called automatic-mill process. A general knowledge of both processes is assumed to be possessed by the reader.

The pilger process is in use chiefly in Europe and the automatic or plug-mill process chiefly in the United States. Experience with both processes has established the following comparable economic features between the two methods:

1 The output in tons with the plug-mill process is two or three times more than with the pilger process.

2 The cost of installation is about the same for either process or is rather less for the plug-mill process.

3 The cost of tool equipment, such as rolls and mandrels, is several times greater with the pilger process than with the plug-mill process.

4 Rolls and mandrels must be of the best grade of alloy steel in the pilger process, and in the plug-mill process they are of similar composition to those used in other steel working methods.

5 Maintenance of plant and tool equipment is much less costly and more simple with the plug-rolling method than with the pilger method.

6 The quality of the tube produced with reference to evenness of wall thickness and smoothness of outside and inside surface is better and more uniformly reliable with the plug-rolling process than with the pilger process.

7 Tube lengths obtained with the pilger-process are currently 40 ft. to 60 ft., and exceptionally up to 80 ft. or 90 ft. With the plug-rolling process, lengths obtained today are 30 ft. to 40 ft; with slight modification of the heretofore usual equipment, it will be possible to produce 50-ft. lengths.

8 The largest tubes produced with the pilger method are 20 in. in diameter and with the plug-mill process about 14 in. diameter. A recent development (expanding) will permit the production of 24 in. diameter and larger with the plug-rolling method.

The belief obtains, to a varying degree in the steel industry, that a better-grade steel (sounder steel) is necessary with the plug-rolling method than with the pilger method. This belief, or contention, is based on the assumption that for the plug-mill operation the billet is pierced to a wall thickness much less than is necessary for the pilger operation. This is an erroneous assump-

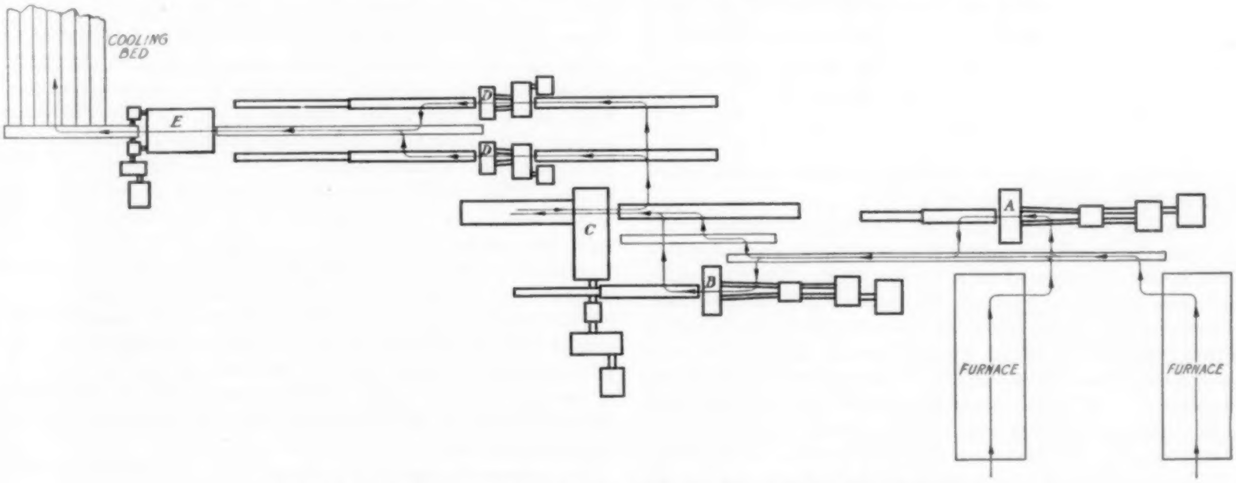

Fig. 1 Diagrammatic Layout of a Seamless-Tube Plug-Mill Unit

[1] Consulting Engineer and Vice-President, The Aetna-Standard Engineering Co.

[2] Assistant Vice-President, The Aetna-Standard Engineering Co.

Contributed by the Iron and Steel Division and presented at the Spring Meeting, Pittsburgh, Pa., May 14 to 17, 1928, of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y. All papers are subject to revision.

tion where tubes of large size are concerned, as in this case the billet is pierced to a wall thickness substantially the same for the plug-mill operation as for the pilger operation.

The contention that better steel is required in the plug-rolling method is partly correct if applied only to the production of smaller sizes of tubes where the billet is pierced to a considerably thinner wall for the plug-mill method than for the pilger method. But in the production of these smaller tubes, a comparatively small-size solid billet can be used in the plug-rolling method, and with the use of small-size solid billets, which have had a large degree of refinement from the ingot down, the difficulties attributable to unsound steel have today practically been eliminated, at least in this country.

### Modern Plug-Mill Unit

The following description and accompanying illustration of a

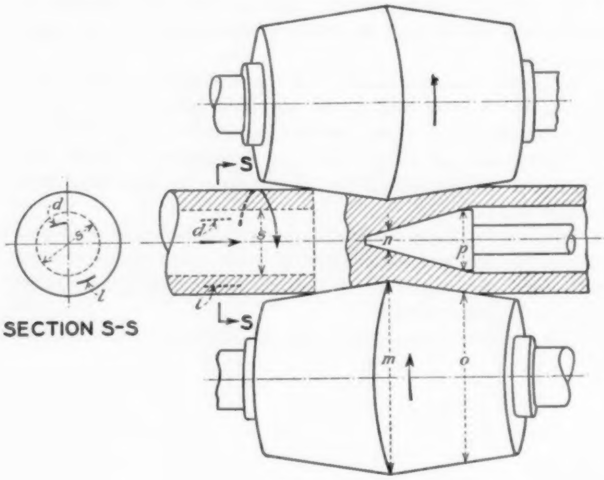

Fig. 2

typical modern plug-mill unit may serve toward a better understanding of the subject. (See Fig. 1.)

Steel billets are charged into the piercing-mill furnaces, and from there into piercing machine *A* or piercing machine *B*, either of which can be operated as a piercer, or the first piercer for piercing only and the second piercer for enlarging the pierced billet.

From either of the piercing machines the billet is conveyed to the plug mill *C*. Here the billet is passed through the rolls two or more times for the purpose of reducing wall thickness and elongating it. All of the movements of the billet are performed mechanically on the plug mill with practically no hand labor.

From the plug mill the tube is conveyed to either of the reeling machines *D*, in which it is acted upon by oblique rolls on the outside and a cylindrical mandrel on the inside, for the purpose of equalizing the wall thickness and smoothing its outside and inside surfaces. In the reeling operation the diameter of the tube is slightly increased, resulting from a slight reduction of the wall thickness.

After the reeling operation, the tube is passed through the sizing machine *E* for the purpose of reducing it to the required diameter. This machine usually contains several pairs of grooved rolls. The tube, after leaving the sizing machine, is shifted onto a conventional type of cooling table consisting of a number of slowly moving conveying chains, rolling the tubes on a slightly inclined table.

### Difficulties With Steel

It is a fact that in the manufacture of seamless tubes, the quality (soundness) of the solid billet is of great importance; and herein lies one of the chief difficulties encountered in this manufacture, whether it be by the pilger process or by the plug-mill process.

Defects may result on the inside of the tube from segregation or blow holes at or near the center of the solid billet, and on the outside of the tube from defective bar-mill practice, or from defects (tears, slivers, and blow holes) at or near the surface of the solid billets.

The defects on the outside of the tube, resulting from faulty bar-mill practice and from tears and slivers on the surface of the solid billet, can be and have been traced to the source, and much improvement has been made in this respect.

### Elimination of Steel Defects

The elimination or reduction in number of defects on the inside and outside of the tube resulting from segregation and blow holes can also be greatly helped, as will be evident from the following:

Inside and outside surface defects attributable to segregation can hardly be eliminated altogether, but such defects can be greatly reduced in magnitude by giving the ingot more rolling, reducing it to a smaller-size round billet than has been customary heretofore for the production of a given size tube.

Inside surface defects attributable to blow holes can be largely reduced in number or entirely eliminated.

Referring to Fig. 2, it will be understood that the piercing mandrel over which the billet is forced explores, so to say, the inside of the solid billet on its full length for defects. An annular outside volume of the solid billet, represented in dotted lines, equal to the volume of the pierced billet, has remained unexplored by the mandrel. Any defect *d* in the explored section *S* of the solid billet, in the shape of what is commonly called a lamination, resulting from a blow hole in the ingot from which the billet was rolled, is laid out or exposed on the inside surface of the pierced billet in the shape of a tear, seam, or lap, while any such lamination *l* existing in the unexplored annular section of the solid billet will remain practically undisturbed in about the same relative location in the annular section of the pierced billet. (Therefore, the smaller the explored section *S* is in relation to the full section of the solid billet, the fewer such laminations may be contained in the displaced central volume of the billet and consequently fewer or no tears, seams, or laps may be obtained on the inside of the pierced billet.)

This condition again points in the direction of using as small a solid billet as possible for the production of a given size tube. It will readily be seen that the explored or central section *S* of the steel billet is rapidly reduced in relation to the full section as the diameter of the billet is reduced, the unexplored section remaining the same.

The logical conclusion to be drawn from the foregoing is that by using a billet larger in diameter than necessary an unusual number of inside defects may result.

The described condition with reference to location of laminations that may or may not result in defects on the outside or inside of the tube should serve as an indication to the steel maker as to where the blow holes should be located in the ingot if they cannot be entirely eliminated. In other words, with reference to Fig. 3, if the inner section *A*, in relation to the full section of the ingot, is the same as the explored section *S* of the solid billet in relation to the full section of the solid billet, Fig. 2, then the blow holes should be located as centrally as possible in the sectional outer area *B* of the ingot in order not to result in injurious outer or inner surface defects in the tube.

A closer cooperation in this respect between the tube-mill operator and the steel maker should result in better conditions as to surface defects in the tube.

With reference to the occurring surface defects on the tube, it is well known that the piercing operation is a test of the steel; piercing means penetrating the center of the billet, spreading the displaced metal of the center toward the outside, at the same time elongating the billet. The spreading and stretching stresses set up in the billet by the piercing operation are hard

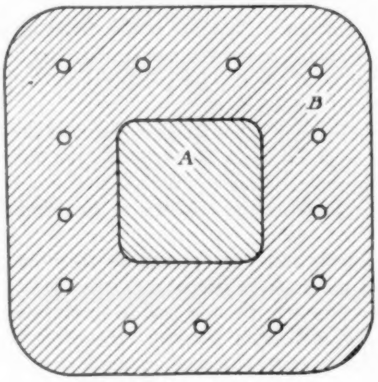

Fig. 3

on the steel and tend to aggravate existing defects in the billet. These stresses, and resulting aggravations of existing defects, are increased in the piercing operation proportionately with a decrease of the wall thickness and an increase of the elongation; and they are decreased proportionately with an increase of wall thickness and a decrease of elongation. Hence, the conclusion is reached that a given size tube should be produced by using as small a billet as possible in order to set up a minimum of stresses and corresponding minimum punishment of the steel.

### Power Consumption

Another way to prove the correctness of this statement is as follows. It is clear that the more power that is used to pierce a billet of a given size in a given time, the more punishment is given to the steel. Now, the power absorbed is represented by the formula: Kilowatt-seconds $= C \times$ weight of billet in lb. $\times$

$$\log\left(\frac{\text{length of pierced billet in feet}}{\text{length of solid billet in feet}}\right)$$

From this formula, in which $C$ represents a constant value, it is evident that the power can be reduced to a minimum by increasing the length of the solid billet and decreasing its diameter correspondingly, maintaining the same weight. All of which results in the fact that by using smaller billets not only is the steel punished to a lesser degree but a considerable saving in power also is obtained.

### Design of Piercing Pass

Until lately there has been no good and reliable procedure established to determine the most favorable size of solid billet from which to produce a given size tube; it has been largely a matter of "rule of thumb." A common practice was to choose a solid billet of a diameter approximately the same, or somewhat smaller, than the desired tube. The correct method to determine the most favorable size of solid billet is as follows.

The piercing diagram illustrated in Fig. 4 is arranged in such a manner that the converging pass $CA$ formed between the rolls establishes enough grip on the billet, by the time the latter has progressed to point $D$, to force it over the point of the mandrel. The elongation of the billet, that is, the reduction of its cross-sectional area, should be done only in the converging pass from $C$ to $A$ with a minimum draft or reduction of the billet. The diverging pass, from $A$ to $B$, between the rolls and the mandrel is arranged so that the cross-sectional area of the billet at $A$ is equal to that at $B$. In a piercing pass established to fill these conditions, the billet is only subjected to expansion in the diverging pass and to elongation in the converging pass.

It will be clear from a closer study of Fig. 4 that the metal of the billet has a fair chance to flow lengthwise (or the billet has a chance to elongate) in the converging pass where it is gripped between the two roll faces forming a comparatively large included angle $a$ between them. But where the metal is gripped between the two diverging roll faces and the two corresponding mandrel faces, it becomes almost impossible for it to flow lengthwise between the respective roll and mandrel faces which form a smaller flow angle $g$ for the metal than is the case in the converging pass. On the other hand, it is evident from the cross-section at $yy$ of Fig. 4 that the flow angle in the transverse direction is greater than in the longitudinal direction, from which it follows that in the diverging pass the metal meets less resistance to flow in the transverse direction (expansion) than in the longitudinal direction (elongation). From this analysis it becomes clear that the diverging pass should logically be determined, as described, so as to compel expansion, and no elongation of the billet, instead of by using a mandrel the shape of which is determined by guess work.

The foregoing procedure of determining the piercing conditions for a given size tube is a sure way to obtain the best results, with reference to punishment of the steel and consumption of power. It constitutes the subject of a pending patent application.

### Conflicting Factors Confronting Management

Since the piercing operation, even if performed under the most favorable conditions, is a very severe test of the steel, it is of

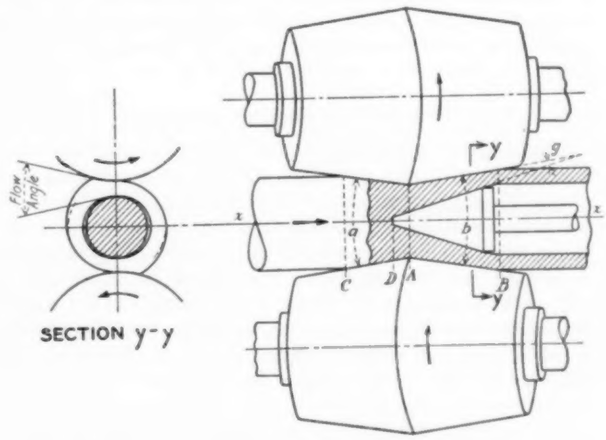

Fig. 4

the greatest importance to make sure that this operation is being performed under conditions as favorable as possible. When it happens that losses occur, that is to say, when defective tubing is produced, a chaotic condition usually arises. The operating management of the tube mill, believing that working conditions have been maintained constant and proper, attributes the loss exclusively to defective metal, whereas the steel maker, believing that the metal is not defective, attributes the losses exclusively to improper conditions in the piercing procedure, a case of "the pot calling the kettle black," and the general management is at a loss where to place the blame. Manifestly it is desirable to eliminate one of the two causes of defective tubing so that

there obtains no more uncertainty as to where to look for the remedy. This can be done by adopting the design of the piercing pass in the manner explained in the preceding paragraph, by eliminating the "rule of thumb" practice.

In the foregoing procedure of determining the most favorable piercing conditions it was assumed that the angles $a$ and $b$ of the converging and diverging passes were given as well as the type of roll, namely, barrel-shaped rolls with their axes practically parallel to the pass line $xx$, a type of roll which has commonly been used in the production of the larger size tubes, say about 5 in. diameter and larger. These angles and the type of roll constitute the elements which determine more or less favorable working conditions and the choosing of them should be given careful consideration.

### Function of Piercing Rolls

It will be noted from Fig. 4 that at the first contact $C$ established between the billet and the rolls, the diameter of the roll is small while the billet is large; as the billet progresses from $C$ to $A$, the diameter or circumference of the billet decreases while that of the roll increases; from $A$ to $B$ the reverse takes place, that is, the diameter or circumference of the billet increases while the corresponding diameter or circumference of the rolls decreases. This irrational relation between corresponding diameters, and consequently speeds, of the rolls and billets at different contact points during the progress of the billet through the piercing pass, results in the setting up of the injurious stresses in the billet heretofore referred to; it also results in the breaking up of the center of the billet before it reaches the point of the mandrel, thereby favoring the penetration of the mandrel into the center of the billet; but it also has the effect of producing enormous friction or slippage between the rolls and the billet on the outside as well as between the mandrel and the billet on the inside. When considering that the metal pressure exerted by the rolls on to the billet may amount to several hundred-thousand pounds, it will be evident at once that much slippage under such great pressure will result in enormous waste of power.

### Function of Piercing Mandrel

The peculiar functioning of the mandrel in the pass of the now customary piercing machine also greatly contributes to the setting up of injurious stresses in the billet. Referring to Fig. 2, it is apparent that the rolls, being obliquely disposed in relation to the axis of the billet or pass, tend to rotate the billet and feed it forward over the mandrel. The axis of the billet and the axis of the mandrel being the same, it is clear that the mandrel has no forward feeding effect on the billet; the billet therefore is fed or pulled or pushed forward on the outside by the rolls while the mandrel on the inside tends to prevent it from moving forward.

Furthermore, it will be noted that to the large diameter $m$ (Fig. 2) of the roll is opposed the small diameter $n$ of the mandrel, while to the small diameter $o$ of the roll is opposed the large diameter $p$ of the mandrel. The torsion and slippage stresses to which the outside of the billet is subject by the speed differences of the rolls, as explained before, are therefore being repeated for the same reasons on the inside by speed differences of the mandrel. All this occurs under the heavy pressure on the metal necessary to displace it from under the contacting surfaces between it and the rolls and mandrel.

What has been stated heretofore with reference to power absorption by slippage or friction by the rolls on the outside of the billet, also applies in connection with the similar great friction or slippage occurring between the mandrel and the inside of the billet.

### Piercing Power

The total power necessary in piercing consists of three main divisions:

1 Power absorbed by machine friction
2 Power absorbed by roll and mandrel friction on the metal
3 Power absorbed by metal displacement.

A careful analysis of the three power divisions would probably prove that, in many cases, the power absorbed by roll and mandrel friction on the metal is far greater than the power absorbed by actual metal displacement.

From the foregoing it becomes evident that the power required in piercing is of injurious character to the steel and that the amount of power required to produce a tube of a given size in a given time represents the measure of punishment imparted to the billet.

The tendency, therefore, should be to reduce the power in piercing to a minimum in the manner described and rather spend a little more power in the bar mill to produce billets of smaller diameter, the additional bar-mill power required being of a beneficial character to the steel, refining it to a higher degree. Thus a threefold advantage will be obtained; better steel, less power consumption, and less punishment of the steel in piercing.

It is possible to improve the conditions obtaining with reference to the occurring torsional and slippage or friction stresses on the outside and inside of the billet with piercing mills of a different type than that which is now customary.

Referring again to Fig. 4, it is possible, for instance, in many applications, to use piercing rolls of different type than those indicated, whereby most of the metal friction in the diverging pass $AB$, the most injurious, can be eliminated. Some headway has been made in this direction and it is probable that much more progress can be made from now on when new capital to be invested in seamless-tube-mill installations may become less hesitant to lend itself to a justified departure from the trodden path.

There are many other interesting and important features in connection with piercing in particular, as well as with plug rolling and reeling, that deserve more study and understanding by those engaged in this manufacture in order to make intelligent decisions when difficulties arise, particularly in case of difficulties with steel. On account of lack of time, it is impossible to undertake at present a complete detailed study of all features; therefore, this article touches only on the most important ones.

The foregoing deals exclusively with the difficulties encountered at times with steel. However, the conclusion should not be drawn that these difficulties are constant and standing in the way of producing seamless tubes as cheap or cheaper than lap-welded tubes. Good yields, varying between 80 per cent and 90 per cent from solid billet to finished tube, are now being obtained when producing lengths of about 30 ft. to 35 ft., which is a creditable result when considering crop-end losses and about 3 per cent furnace loss.

### Expanding

Another inconvenience inherent in the now usual seamless plants lies in the fact that when it is necessary to change production from one size of tube to another, considerable time, five hours or more, is lost in making the necessary shift in the machine equipment and size of solid billet.

Great advantages can be obtained in this respect by replacing the now commonly used reeling machine with an expanding machine which may function the same as the present reeling machine or may be used to expand the tubular body coming from the plug mill, or from the piercing machine, into larger

sizes of correspondingly thinner walls. Sufficient experimental work has been done to justify the assumption that this expanding method will permit the production of large size tubes up to about 24 in. diameter at comparatively little additional power requirement and with an initial plant cost equal to the cost of a plant for the direct production of tubes with the now usual plug-mill process up to about 14 in. diameter. Allowance for additional cost of larger finishing equipment will, of course, have to be made.

The benefits obtained from the expanding mill will become evident by a study of Fig. 5. A tubular body of 14 in. diameter and wall thickness *d*, coming from the plug mill or from the piercing mill, is expanded to 24 in. diameter of corresponding wall thickness *e*. If a tube of less than 24 in. diameter should be required, for instance, of a diameter as shown by dotted line, it

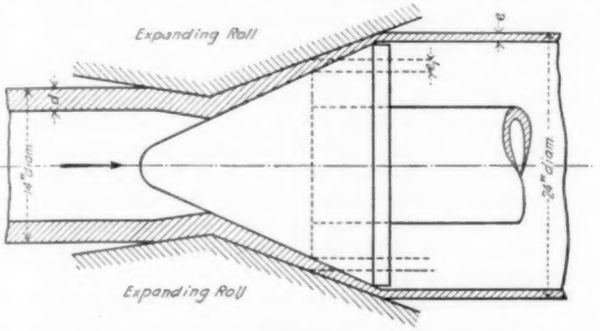

Fig. 5

could be produced without changing the setting of the rolls of the expanding mills by simply using a smaller expanding mandrel, as shown by dotted lines. This smaller tube, however, would have a wall thickness $e_1$, in the same proportion greater than $e$ as its diameter is less than 24 in. Should the wall thickness of the smaller tube have to be less than $e_1$, then it could be obtained by simply preparing a tubular body at the plug mill or piercing mill of the same diameter (14 in.), but of correspondingly less wall thickness than $d$. On the other hand, if the wall thickness $e_1$ should be required to be greater than shown, then the wall of the entering tube would have to be correspondingly greater than that shown and designated by $d$.

It will be seen, therefore, that with the roll setting shown, tubes of varying diameter and wall thickness can be obtained at the expanding mill from a tubular body of constant diameter of 14 in. but of different wall thickness.

The same advantages with reference to simplification in the production of different sizes which are described in the foregoing grouping of sizes from 14 in. to 24 in. obtain when grouping other sizes as, for instance, all sizes from 8-in. to 14-in. diameter and all sizes from 5-in. to 8-in. diameter.

It must be noted here that the indicated division of all sizes of tubes from 5 in. to 24 in. in diameter into only three groups, each to be produced from only three different tubular bodies of constant diameters, was given as an illustration only, and that it will be advisable to arrange the working program for more than only three groups in order to obtain the best possible piercing condition for one size of tube of each group and not too much deviation from the best piercing conditions for all the other sizes of each group.

This great flexibility in sizes obtainable from an entering tube of constant diameter dispenses with changes of guide and roll settings at the plug mill and at the piercing mill. The variation required in the wall thickness $d$ of the entering tubular body can be obtained at the plug mill and piercing mill by a simple change of mandrels. At the expanding mill a change in the setting of the outlet guides would be required to accommodate the varying diameters from 14 in. to 24 in. of the outgoing tubes, but no change of the inlet guides would be required, the entering tube being of constant diameter. Changes in the settings of the reeling machine and sizing machine would have to be made in the same way as in the present installations.

Referring to Fig. 6, a modification of Fig. 5, the expanding mandrel is provided with two different cones *A* and *B*, cone *A* forms a converging pass for the entering tube wall between it and the expanding rolls, and cone *B* forms a parallel pass for the tube wall between it and the expanding rolls. On cone *A*, the entering tubular body has its wall reduced and its diameter enlarged, and on cone *B* the wall is smoothed out in exactly the same manner as is now the case in the customary reeling machine. By the use of this modified mandrel, the expanding and reeling operations may be performed simultaneously in the thus-formed expanding-reeling pass.

The expanding method referred to forms the subject of U. S. Patents.

In the now customary plug-mill installations, the practice is frequently to change the size of solid billet when producing tubes of different diameters. With the use of the expanding mill, the requirement of billets of many different sizes would disappear, only a few standard sizes of billets becoming necessary.

The advantages resulting from such a standardization in the working of steel in the hot state needs no comment.

The benefits obtainable with the expanding mill apply equally well to pilger-mill installations. In fact, these benefits will be more pronounced in a pilger-mill plant than in a plug-mill plant, for the reason that a standardization to fewer sizes of the much more expensive equipment in rolls and mandrels, necessary for a pilger-mill plant, will result in far greater economy than in a plug-mill plant. These benefits can be summarized as follows:

1 The expanding mill can be used for the same purpose as the now commonly used type of reeling mill, or it can be used to reduce the wall thickness and increase the diameter of the tube; or it can be used to accomplish both—expanding and reeling simultaneously.

2 Comparatively little power is required, for the reason that the character of impingement on the steel by the expanding

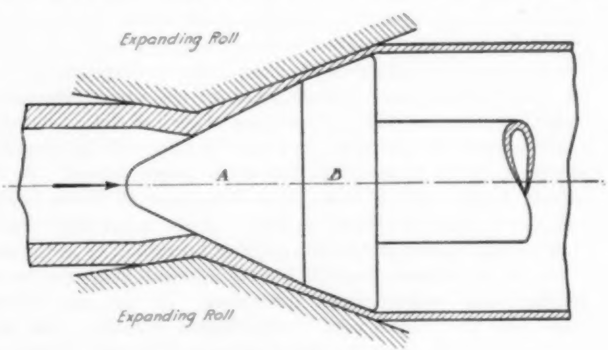

Fig. 6

rolls is much more favorable with reference to "flow of metal" than is the case if, in the absence of the expanding mill, the same reduction of wall thickness would have to be made at the plug mill or pilger mill.

3 A thicker wall can be produced at the plug-mill or pilger-mill operation.

4 A thicker wall can be produced at the piercing operation; hence, less punishment of the steel and less aggravation of existing defects in the billets.

5 On account of being able to produce thicker walls at the piercing-mill and plug-mill or pilger-mill operations, these operations become easier and, as a result, should favor more output.

6 Time is saved when changing from one size to another.

7 Fewer sizes of solid billets are required.

8 The equipment required for the production of the tubular body at the piercing mill and plug mill or pilger mill becomes standardized to few sizes (diameters).

9 The expanding mill can be added to any kind of existing installation suitable to produce hollow blanks, thus enabling the production of larger tubes with existing equipment at comparatively little cost.

### Output, Cost, and Quality

The output in a modern plug-mill plant in tubes of 5 in. diameter and larger is about 200,000 tons per year.

The cost of production of seamless tubes of usual sizes is the same as, or less than, that of lap-welded tubes. Inasmuch as the seamless-tube industry is comparatively new, it is reasonable to assume that more progress will be made with reference to cost of production.

The method of manufacturing seamless tubes permits the use of high carbon steel or alloy steel, resulting in a product of superior quality, with reference to strength and usage. It is also applicable to other metals such as copper, brass, aluminum, etc., all of which are impossible by the welding process.

## Discussion

H. H. Murray.[3] This is a very interesting general account of the process of the manufacture of seamless tubes in what might be referred to as the larger sizes. There are, however, several points which give ground for further discussion.

Taking first the question of the relative merits of the pilger and plug-mill processes—while the writer is a firm believer in the superiority of the plug-mill process, it is well sometimes for us to analyze our views lest they be tainted with prejudice—the pilger process is, and has been for a number of years, very largely used in Europe, whereas the automatic or plug-mill process has made little progress except in the United States. While the Europeans in our opinions may be somewhat backward in some directions, there must be some good reason for their preference for the pilger method of manufacturing seamless tubes. There are two installations of pilger mills for large-size pipe in the United States, and it might be of interest to get expressions from those familiar with the operation of each of these two mills. The statement is made that the output in tons with the plug-mill process is two or three times that of the pilger process. In the output of every mill there is a controlling factor or "bottle neck," and in the plug mill shown in Fig. 1 of the paper this "bottle neck" would apparently be the piercing operation, or in the case of the use of piercers $A$ and $B$, piercer $B$, which performs the expanding and wall-reduction operations. In the case of the pilger mill the "bottle neck" is the rolling operation, but as a general rule more than one pilger rolling mill is used in conjunction with one piercing mill. The statement is made that the cost of installation is about the same for either process; but considering that the pilger mill generally consists of a piercer and one or more sets of pilger rolls, and sometimes reeling machines, it is believed that such an installation should not cost any more but would probably cost less than a layout with two piercing mills as shown in Fig. 1. Regarding the cost of tool equipment, rolls, mandrels, and maintenance, there is nothing to say, as it is generally conceded that in the case of the pilger mill this cost is higher than in the case of the automatic mill. Regarding the quality of the tube, while as a whole plug-mill tubes are of better quality than tubes from the pilger mill, in certain details a pilger-mill tube is superior. One of the great troubles of the plug-mill operator is the elimination of internal scratches. The pilger mill overcomes this difficulty, making a tube with a very fine inside surface, but the outside surface of such tubes does not compare with a tube made on a plug rolling mill. The writer would like some reliable information as to actual tonnage output on a modern pilger mill where two rolling mills used in conjunction with the piercer are making long tubes of a size and length to give maximum output.

Regarding the question of steel quality, the defects which give the seamless-tube manufacturer trouble exist in the billet, of course, and are exposed as stated by the authors in the piercing operation. In the case of the pilger mill the tubes are pierced with a very heavy wall and are reduced to the required thickness in the pilgering process, which is almost equivalent to a forging operation, and this tends to close up and conceal many defects. In the installation referred to by the authors the general idea would be to pierce a wall of the same thickness as would be pierced on the pilger mill and to reduce this wall thickness in a subsequent piercing machine designed for expanding and wall-reducing operations. Whether this would hide these defects to the same extent as the other operation, however, the writer is not prepared to say.

The authors state that the difficulties experienced in seamless-tube manufacture should not lead us to draw the conclusion that seamless tubes cannot be produced as cheaply as or cheaper than lap-welded tubes. All of us who manufacture seamless tubes are looking forward to the time when this will be accomplished, but at the moment, excepting in perhaps a few individual cases, this has not been generally accomplished. Most of the seamless-tube mills in existence were designed to take care of a more or less general business of varying sizes and types of tubes, whereas lap-weld mills as a rule, due largely to the enormous requirements of the oil industry, are built to give a maximum output on a narrow margin of sizes processed in large quantities. When the hesitancy of capital referred to by the authors has been overcome, perhaps we may have seamless mills built along these latter lines; and when that time comes we should be well able to meet the lap-weld man on his own ground. In this connection, of course, we should not lose sight of the fact that at the present time raw material of a quality suitable for making seamless tubes is more expensive than skelp for lap-welded tubes. The very fact that seamless tubes require a superior grade of material for their successful manufacture, as compared with the material which may be used for lap-welded tubes, although disadvantageous from a cost point of view, is of considerable advantage to the consumer in the matter of intrinsic quality.

J. B. Wharton.[4] Reference is made in this paper to the quality of steel required to produce seamless tubes by the pilger and automatic-mill processes. It was stated that for the tubes of larger diameter, say above 6 in., the quality of steel required is the same. A brief description of the two processes may be helpful in determining whether this is the case.

For the pilger process, cast round ingots, always considerably larger than the finished tube, are used. These ingots are reheated and pierced. The inside diameter of the pierced blank is approximately the same as will be the inside diameter of the finished tube; the outside diameter, however, is 3 to 4 in. larger than will be that of the finished tube. The pierced blank is

[3] Superintendent, Babcock & Wilcox Tube Co., Beaver Falls, Pa. Mem. A.S.M.E.

[4] Chief Engineer, Standard Seamless Tube Co., Ambridge, Pa.

then forged down in the pilger mill to the desired outside diameter. This operation tends to forge out and cover up any defects developed in the piercing operation.

For the automatic-mill process, rolled rounds are used. The diameter of the round is much smaller than the finished tube. The initial piercing leaves a heavy wall comparable to the pierced blank for the pilger mill. The diameter of the pierced blank is still much smaller than the finished tube.

In the second piercing operation the blank is expanded 30 to 40 per cent in diameter, is elongated 50 to 100 per cent, and the wall is reduced to a thickness of about 50 per cent greater than that of the finished tube. The second piercing operation therefore not only aggravates any defects developed in the first, but uncovers others which may have been in the steel and not brought out in the first piercing.

As opposed to a reduction in diameter in the pilger process, there is an expansion in diameter in the automatic-mill process. It would therefore seem clear that a better quality of steel is required for the automatic process than for the pilger.

The writer understands that the power formula, kilowatt-seconds $= C \times$ weight of billet $\times \log \dfrac{\text{length of pierced billet in feet}}{\text{length of solid billet in feet}}$, was developed before heavy-wall piercing became general practice and has not been thoroughly tested for heavy-wall piercing. The writer has made a few experiments along this line and has been unable to obtain reasonable results.

By taking power charts on piercing various sizes of tubes and solving the formula for $C$ we ought to get a reasonable relation between the various values of $C$. The results of such a calculation follow:

$8^5/_8$-in. $\times$ 32-lb. casing, $C = 97.4$
$9^5/_8$-in. $\times$ 36-lb. casing, $C = 126.2$
$11^3/_4$-in. $\times$ 60-lb. casing $C = 83$
$13^3/_8$-in. $\times$ 61-lb. casing $C = 305$

However, very consistent results on the power required to expand a pierced billet have been obtained. The method used was the determination of the power required to displace a given volume of metal per second. The results and method of procedure are shown in Table 1 and Fig. 7.

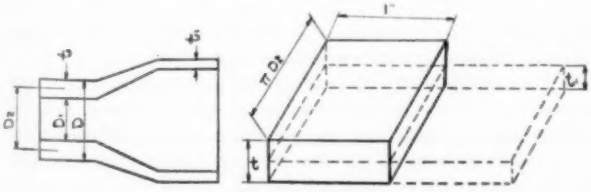

FIG. 7

$\left(\frac{\pi D^2}{4} - \frac{\pi D_1^2}{4}\right) - \pi D_2 t_1$ = volume of metal displaced per unit of feed of billet, or when all dimensions are expressed in inches and time in seconds the results will be kilowatts per cubic inch of metal displaced per second.

By referring to Table 1 we find that the kilowatt per cubic inch of metal displaced per second varies from 11.5 to 14.2. This result is reasonably close when we consider the fact that no attempt was made at temperature control other than the furnaceman's judgment.

The disk type expanding mill has, the writer believes, been used successfully in this country as a reeler by one pipe manufacturer. Its theoretical action is, however, more nearly correct for an expanding operation than for a reeling operation. By referring to Fig. 8 it will be seen that the speed of the disk at diameter D at beginning of reeling cone is less than the speed of the disk at diameter D at end of reeling cone, while the diameter of the pipe remains practically constant. It can readily be seen that this condition produces a constant slip between disk and tube.

The following calculations show the method of arriving at the results given:

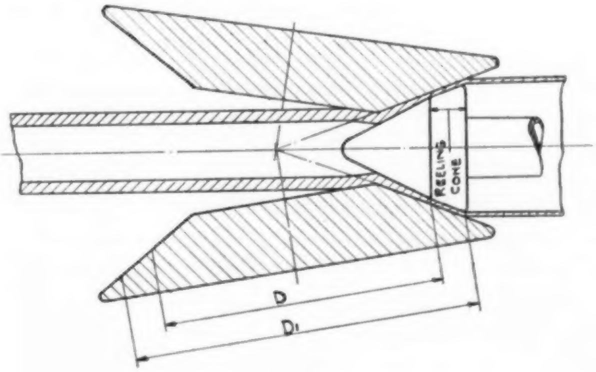

FIG. 8

$8^5/_8$ in. $\times$ 32-lb. casing
$L_1 = 8.3$
$L = 11.57$
$W = 935$
$S = 11.4$
$KW = 1150$

$$C = \frac{1150 \times 11.4}{935 \times \log 1.392} = \frac{1150 \times 11.4}{935 \times 0.1433} = 97.4$$

$9^5/_8$ in. $\times$ 36-lb. casing

$$KWS = C\ W \log \frac{(L)}{(L_1)}$$

$$C = \frac{KWS}{W \log \dfrac{(L)}{(L_1)}}$$

$KWS$ = kilowatt-seconds
$C$ = constant
$W$ = weight of steel in pounds
$L$ = length of pierced billet in feet
$L_1$ = length of solid billet in feet
$L_1$ = 8.1 ft.
$L$ = 10.4 ft.
$W$ = 1060
$S$ = 13.2 sec.
$KW$ = 1100

$$C = \frac{1100 \times 13.2}{1060 \times \log 1.282} = \frac{1100 \times 13.2}{1060 \times 0.10788} = 126.2$$

$11^3/_4$ in. $\times$ 60-lb. casing
$L = 13.4$
$L_1 = 8.0$
$W = 1712$
$S = 13.46$
$KW = 2400$

$$C = \frac{13.4 \times 2400}{1712 \times \log \dfrac{13.4}{8}} = \frac{13.4 \times 2400}{1712 \times \log 1.67} = \frac{13.4 \times 2400}{1712 \times 0.2227} = 83$$

$13^3/_8$ in. $\times$ 61-lb. casing
$L = 8.6$

$L_1 = 7.58$
$W = 1825$
$KW = 2350$
$S = 12$

$$C = \frac{12 \times 2350}{1825 \times \log 1.135} = \frac{12 \times 2350}{1825 \times 0.0549} = 305$$

W. M. Selkirk.[5] Ever since the inception of seamless tubes we have heard that the industry is in its infancy. The last few years, however, have seen very rapid strides in the way of development of the art of manufacturing them.

As stated by Messrs. Stiefel and Pugh, the piercing operation is a very severe test of the quality of steel. This is especially true where light-walled hollow blanks, such as are required under the present operating conditions for the plug mill, are to be produced. Steel cast ingots pierced with heavy walls have been used in Germany in connection with the plug mill, but this practice involves as many as 18 passes in the mill, also reheating and sawing of the rolled billets between certain passes in order to produce a hot-finished tube of commercial size and quality for general use, a procedure which would not be considered economical in this country.

I have been much interested in the authors' references to the expanding process. It is apparent that by means of this process a pierced blank with a much heavier wall would be necessary for the production of all classes of seamless tubes. This condition would be very much more favorable for the use of cast ingots for the plug mill, as well as for the pilger mill. It is also apparent that by this process, which renders possible the standardization of sizes of pierced and rolled tubes prior to the expanding, a great deal of equipment, especially that used in connection with the pilger process, could be eliminated. I am of the opinion that this method if put into practice would demonstrate a decided advancement in the manufacturing art.

A comparison has been made between the plug-mill process and the pilger-mill process. It might be interesting to know that while it is customary to produce a light-wall hollow blank for the plug mill, the pilger mill demands a billet with a heavy wall, rendering the use of cast ingots possible. It might also be of interest to know that tubes over 130 ft. in length have been produced on the pilger mill in this country.

While this displays a certain economy with regards to scrap loss, cropping, etc., the commercial value of tubes of such length is questionable, due principally to handling and transportation difficulties. It might be said that the length of tubes possible to roll by the pilger mill is limited only by the size of ingot it is practical to heat and pierce.

I have studied with a great deal of interest the paper submitted by Messrs. Stiefel and Pugh and wish to congratulate them on the very able and interesting way in which they have described the manufacture of seamless tubes.

[5] Chief Engineer, Seamless Tube Division, Pittsburgh Steel Co., Monessen, Pa. Mem. A.S.M.E.

W. R. Clark.[6] The writer's experience in piercing has been confined entirely to brass and copper. However, further light on one or two things with reference to the power requirements presented in this paper would be valuable. The first formula gives a kilowatt-second equal to $C$ times the weight of billet in pounds times the logarithm of the length of pierced billet in feet divided by the length of solid billet in feet. The writer's understanding is that this expression applies only to the power necessary to move the material in the billet itself, irrespective of any friction applied in the mill or friction applied by the rolls and the plug to the outside and inside surfaces of the tube being rolled.

We have noted that if a piercing point is introduced too far into the mill, the power requirement goes up materially, resulting from increased friction, caused by a slowing down of the feed of the billet, that friction being manifest in increased power per pound of billet rolled per minute.

W. Trinks.[7] The writer has noticed that in European mills for piercing billets, the angle of the roll is adjustable when looking at the plan view, whereas it is fixed when looking at the elevation. In American mills the reverse is true. There must be some reason. The writer would like an explanation from Messrs. Stiefel and Pugh as to the reasons for this.

Furthermore, a study of available literature shows that there is a difference in the angle of the conical rolls. In some rolls the entering angle is large and the leaving angle is small, whereas in other rolls the opposite is true. Again, is that something that just happens or is there a reason for it?

# Mechanical Properties of Aluminum Casting Alloys at Elevated Temperatures

By R. L. TEMPLIN,[1] C. BRAGLIO,[2] and K. MARSH,[3] PITTSBURGH, PA.

*The investigational work described in Part I of the paper includes tensile results obtained from "short-time" high-temperature tests of ten different aluminum casting alloys and very pure cast aluminum, and for various heat treatments in the case of some of the alloys. All the specimens tested were sand cast and include the more common commercial casting alloys of aluminum.*

*Tensile strength, yield point, elongation in 2 in., reduction in area, and Young's modulus values are given for various temperatures throughout the range 75–800 deg. fahr. A typical set of stress-strain curves are given for one alloy, and detail curves showing the effects of temperature on the tensile strength, yield point, and reduction in area for all the materials discussed. An average curve and formula are given, showing the effects of temperature on Young's modulus for all aluminum alloys.*

*Data are presented to show how certain effects of temperature on aluminum alloys susceptible to heat treatment may be appreciably modified by still further heat treatment or artificial aging. A method is indicated for applying experimental results from a single lot of specimens to commercial-product average values, together with a complete table of recommended tensile-property values at various temperatures for the alloys tested.*

*The second part of the paper describes the original heating equipment, the alternate tests and alterations to equipment to determine and improve the temperature uniformity throughout the specimen; also the method of measuring the specimen temperatures during tensile tests, data being presented to substantiate the reliability of this method.*

*Consideration of the results of temperature-distribution tests made with the final arrangement of the heating equipment and the temperature-measuring equipment used for tensile tests, indicates that an accuracy of temperature measurement of plus or minus 1 per cent and a maximum temperature differential throughout the specimen of 10 deg. fahr. are obtained.*

## Part I[4]—Tests and Results

THE increasing use of cast aluminum alloys in structures or machines designed to function at elevated temperatures has demanded a better knowledge of the mechanical properties of the alloys throughout the temperature ranges obtaining. This need has been appreciated by many other investigators, as shown by the results appearing in the technical literature,[5] but a careful review of such data emphasizes the fact that in most cases the materials tested were non-commercial in this country, the methods used were open to serious criticism, or both. This conclusion seems to be in accordance with the findings of the Joint Committee of this Society and the American Society for Testing Materials, as shown by their symposium[6] and more recent report.[7] With all due respect to the valuable work done and planned by this committee, the authors are giving the results of their investigational work, qualifying it extensively by describing in careful detail the methods and apparatus used in testing and the treatment accorded the data obtained.

### Purpose and Scope of the Work

The work described in this paper had as its purpose the definition of the tensile properties of the more common casting alloys of aluminum throughout the elevated temperature ranges where they could be used satisfactorily. Data are given for ten different casting alloys, very pure aluminum, and for different heat treatments in the case of some of the alloys. In general, the tensile properties have been given throughout the temperature range 75–800 deg. fahr. In nearly all cases tests have been made at still higher temperatures, but the range just indicated covers the temperatures of interest to the designing engineer since the structural use of the alloys at temperatures above 800 deg. fahr. is not recommended.

The tests made were all of the so-called "short-time" type in which the specimen is pulled soon after temperature conditions have reached a practical equilibrium. Such a type of

high-temperature test has limitations, but gives a reasonable basis for comparing different alloys and materially assists in a better selection of material for use at the higher temperatures.

## Methods and Apparatus Used

Before this work was done, much time and effort were spent in developing suitable apparatus for use in making the tests. Particulars of the furnace used, together with a brief description of its development and final calibration, are given in the second part of this paper by Mr. K. Marsh, who was responsible for many of the details of the final design, as well as for the electrical control panel. The tests were all made with a 1,000–10,000-lb. capacity Olsen wire testing machine, using the smaller capacity range whenever possible. Special head blocks were fitted to the machine and the extension holders with spherical-seat nuts shown in Fig. 1 provided. For the stress-strain tests the extensometer shown in Fig. 2 was used. The extensometer consists essentially of a steel rod inside of a steel tube of the same length, with a Y-shaped yoke rigidly attached to the lower end of each. The upper end of the tube is partially closed and carefully machined at three points so as to center and guide the inner rod. A small taper pin is provided to locate the rod and tube with respect to each other when applying the instrument, so that the lower clamps will be 2 in. apart. A guide rigidly clamped to the upper end of the top extension holder, is arranged so as to keep the instrument in proper position during use without restraining it from functioning as intended. This device proved very satisfactory for the materials tested, although it might not be sufficiently sensitive for similar tests of the ferrous metals due to their higher modulus values. The small clamps and screws at

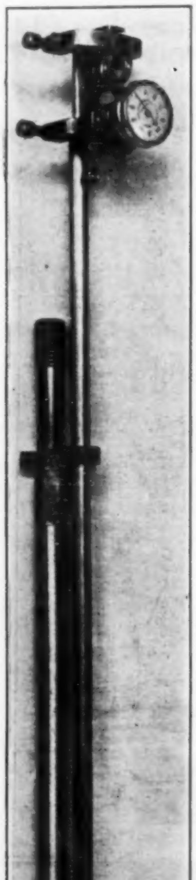

Fig. 2 Extensometer Used in Stress-Strain Tests

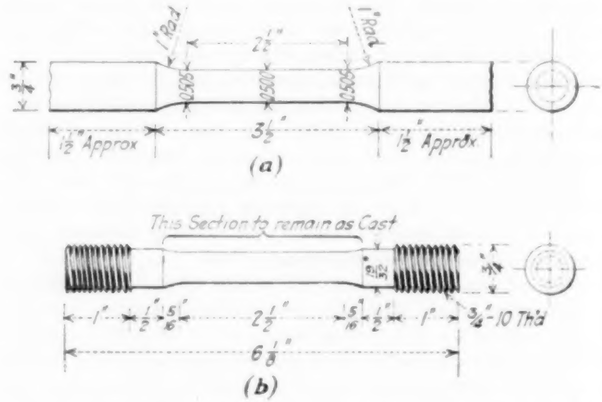

Fig. 3 Dimensions of Specimens as Cast (a) and as Machined (b)

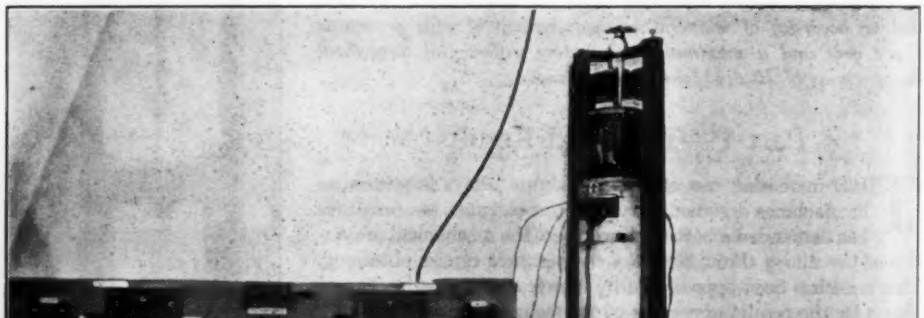

Fig. 4 Complete Assembly of Testing Machine, Furnaces, Control Panel, Temperature-Measuring Instruments, and Extensometer

the lower ends of the instrument are made of high-speed steel and gave no trouble due to oxidizing or annealing up to temperatures of 850 deg. fahr. The upper part of the instrument is a 2-in. Riehlé extensometer, one arm of which attaches to the outer tube and the other arm to the inner rod of the lower part of the instrument.

The specimens used were sand cast to the dimensions shown in Fig. 3(*a*), then machined to dimensions as shown in Fig. 3(*b*). These dimensions conform to the A.S.T.M. standard specimen for sand-cast metals. It should be noted that no machining

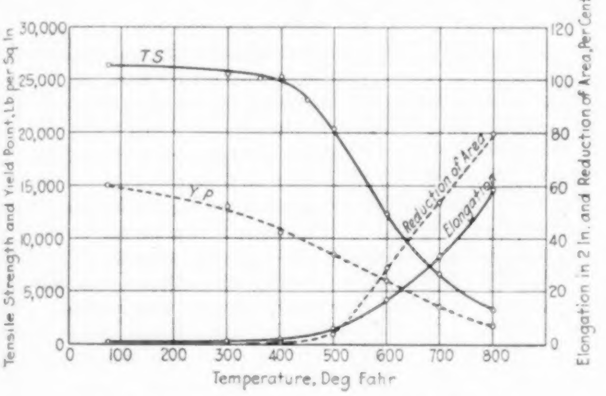

Fig. 5 Test Data of Alloy No. 109 as Cast

was done on the reduced portion or gage section of the specimens other than to file off occasional projections at the parting line of the mold. The specimens were cast under the supervision of Mr. R. S. Archer, at the Cleveland Works of the U. S. Aluminum Co. From 30 to 40 specimens were cast from the same lot of metal under carefully controlled conditions of melting, temperature, and casting so as to produce as uniform a set of specimens as possible for each alloy tested. In some instances such procedure gave mechanical properties at room temperature that were slightly higher than the commercial averages; in others they were slightly lower, but in no case was the deviation serious. Before making the tests at the higher temperatures each lot of specimens was carefully analyzed to make sure that their chemical composition closely approximated the nominal composition indicated for the alloy. The analyses of the specimens tested are given in Table 1.

In preparing a specimen for testing, the identification numbers were stenciled on the ends, the reduced section was measured, and two sets of 2-in. gage marks, staggered about $^1/_4$ in., were placed on it. The specimen was then screwed into the top extension holder and the holder held in a bench vise while the "beads" of the top and bottom thermocouples were clamped on the shoulders of the test specimen. Small pieces of asbestos paper were inserted between the thermocouple beads and the clamps to prevent radiation effects from the furnace walls. Fig. 1 shows a test specimen in the holders with thermocouples attached. The specimen was then screwed into the bottom specimen holder within the main furnace, and the top of the main furnace and the top end furnace replaced. The thermocouple wires were next connected to the recording instruments, the line current turned on, and the furnace rheostats adjusted, using the ammeter and calibration chart in order to obtain the desired temperatures in the main and end furnaces.

The approximate time required to heat the specimen to the desired temperature was about two hours. Occasionally it was necessary to make a slight adjustment of the rheostats so as to get the final testing temperature. The specimen was kept at the required temperature for about thirty minutes and then stressed to failure, the speed of the testing-machine pulling head being 0.107 in. per min. After the maximum load on the specimen was obtained and the specimen broken, it was removed from the furnace and the elongation and reduction of area measured.

For obtaining proportional-limit, yield-point, and modulus values the specimen was placed in the furnace with the special temperature-tensile extensometer attached to it. Upon reaching the proper temperature and remaining constant at that point for thirty minutes, stress-strain data were obtained by applying uniform increments of load and measuring the deformation by means of the special extensometer. The complete assembly of testing machine, furnaces, control panel, temperature-measuring instruments, and extensometer is shown in Fig. 4.

In most instances the tests at each temperature were made in triplicate, and the results of each test at a given temperature did not vary from the average of the three tests by more than ±4 per cent. This is evidence of uniformity both in the making of the specimens as well as in the test conditions. The temperatures recorded as being those at which the specimens were tested, are those obtained from the thermocouples clamped on the specimen, measured with the indicating galvanometer. The recording instrument was used as a check on the furnace conditions, for control purposes, and as a log of the time involved in making the tests.

## Discussion of Results

The tensile-strength, yield-point, reduction-of-area, and

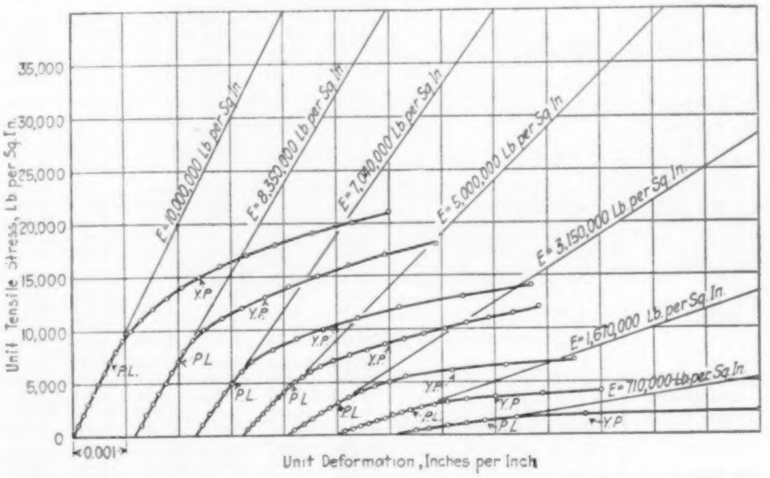

Fig. 6 Stress-Strain Curves for Alloy No. 109 (as Cast) at Various Temperatures

elongation values obtained in the case of each set of specimens tested were plotted as ordinates against temperature in degrees fahrenheit as abscissas. A typical set of such data for alloy No. 109 is shown in Fig. 5. The stress-strain curves obtained at the various temperatures for this same alloy are shown in Fig. 6, and are representative of similar data obtained from the tests of the other alloys. The yield-point values indicated on the curves correspond to the stresses at which the curves have departed from the initial modulus line produced by an amount equal to 0.1 per cent. This value is slightly less than that recommended by one of the authors in a recent paper before the American

TABLE 2 MECHANICAL PROPERTIES OF CAST ALUMINUM AND ALUMINUM ALLOYS AT DIFFERENT TEMPERATURES

| Alloy | Property | Temperature, Deg. Fahr. 75 | 200 | 300 | 400 | 500 | 600 | 700 | 800 |
|---|---|---|---|---|---|---|---|---|---|
| Pure aluminum as cast | T.S., lb. per sq. in. | 7350 | 6500 | 4800 | 3550 | 2500 | 1650 | 1050 | 600 |
| | Y.P., lb. per sq. in. | 2000 | 2000 | 1900 | 1800 | 1600 | .... | .... | .... |

[1] Aged 48 hours at 400 deg. fahr.
[2] Aged one week at 400 deg. fahr.
[3] Aged 113 hours at 200 deg. cent. (392 deg. fahr.).

**Society for Testing Materials.[8] It was considered that the use of such an empirical scheme for determining this property might answer for comparative purposes in the present investigation. Similar stress-strain curves were determined for all of the other lots of specimens tested, but on account of space limitations they have not been included here. The curves showing the effects of temperature on the tensile strength, yield point, reduction of area, and elongation for the other alloys are given in Figs. 8 to 21, inclusive. In all of these curves the points indicated as defining the curves are the actual test results in every case, but are not in strict agreement with the values shown in Table 2, as will be explained later.**

**It was found from the tests that the values of the modulus of elasticity obtained were appreciably affected by temperature as well as by the precision of the extensometer and the temperature-measuring apparatus used. With this in mind and after a careful review of the modulus values obtained from all the tests, it seemed advisable to average the values for all the materials at each temperature, giving the resulting curve shown in Fig. 22. Reference to this curve shows that these average values approximate very closely a straight line which is defined by the formula:**

$$E = 11{,}200{,}000\left(1 - \frac{T}{890}\right)$$

**in which $E$ = Young's modulus of elasticity in lb. per sq. in., and**

**$T$ = temperature in degrees fahrenheit throughout the range 0–890 deg. fahr.**

**From a comparison of the tensile-strength and yield-point curves shown for the various alloys tested, it is clearly seen that these properties decrease with increasing temperature. Certain characteristics of the test results obtained from these alloys permit them to be divided into three groups. The first group consists of No. 7A or very pure aluminum, and Nos. 106, 47, and 43 alloys, all of which are low in copper. The second group consists of Nos. 122, 109, and 142 both in the "as cast" and "heat treated" conditions, and No. 121; this group containing the alloys which are apparently best suited for use at the higher temperatures and which have a higher copper content. The third group consists of Nos. 195, 196, and 112 alloys, and contains those alloys that do not follow the general trend of the previous groups in their behavior at the various temperatures. Results are also shown for the alloys of this group after further artificial aging, whereupon the characteristics peculiar to this group as shown in the preliminary tests are largely eliminated.**

**In general, the first group of alloys, including the very pure**

[8] "Methods for Determining the Tensile Properties of Thin Sheet Metals," by R. L. Templin. Proc. A.S.T.M., part II, vol. 27 (1927), p. 235.

aluminum, shows an appreciable effect of temperature on their mechanical properties beginning at or near room temperature. The second group of alloys does not show such appreciable effects until temperatures in the neighborhood of 400 to 500 deg. fahr. are reached, after which the temperature effects are rather pronounced.

The third group of alloys includes essentially those which are susceptible to artificial aging or secondary heat treatment, and when the tests of such alloys are made at or near temperatures corresponding to their aging temperatures, marked differences are observed in the test results obtained. This is very clearly shown in Figs. 12, 17, and 19. However, the "kinks" in the tensile-strength and yield-point curves for these alloys are almost eliminated by artificial aging of the specimens, at suitable temperatures, subsequent to the initial heat treatment, as shown in Figs. 13, 18, and 20. It will be noted that the curves just referred to are in many respects similar to those obtained from the tests of the second group of alloys previously referred to. Specific consideration has been given to these apparent irregularities in the temperature-tensile curve because they have been observed in similar data reported by other investigators, unaccompanied by adequate, if any, explanation. The present data would appear to emphasize the necessity for further tests of metals that show similar characteristics when tested at elevated temperatures.

In applying the results obtained from the tests just discussed to commercial product of the same nominal composition, a procedure was followed that appears to be somewhat different from any hitherto indicated by other investigators. From the results of many routine tests—in some cases thousands—obtained from the control laboratories of our casting plants, average values for the tensile properties of a given alloy were obtained. These values were accepted as representative of the various alloys, and are indicated in Table 2 as being the properties at 75 deg. fahr. or room temperature. The tensile properties obtained from the results of the investigational work on the representative lots of specimens for each alloy were then replotted in the form of ratio curves to show the ratio of the property at a given high temperature to that of the same property at room temperature, expressing the result as a percentage value. For example, the tensile strength of a given alloy as determined from the experimental tests at 500 deg. fahr. may have been found to be 80 per cent of the tensile-strength value for similar specimens from the same lot tested at room temperature. In order to obtain a satisfactory value for tensile strength for the commercial run of material of this same alloy, at 500 deg. fahr., the average tensile strength obtained from routine commercial tests has been multiplied by 0.80 to obtain the desired value. This procedure has been followed in the case of each material tested, for the various temperatures indicated, and the results are given in Table 2. It will be observed upon comparing the values in this table with the actual test results obtained in the curves, Figs. 5 to 22, that no serious discrepancies occur. Furthermore, the values indicated in Table 2 are those recommended for consideration in determining the suitability of the various alloys for use at temperatures ranging from 75 to 800 deg. fahr.

In using the data given in Table 2, it must be remembered that these values were obtained by the "short-time" method and therefore may not be in strict accordance with similar mechanical-property values that would be found when using a greater time factor during testing. In selecting actual design values for the different alloys considerable engineering judgment in choosing proper safety factors is necessary when using mechanical-property values obtained from the short-time tests. The values indicated, however, would appear to furnish a reasonable basis for comparing the various alloys investigated.

# Part II[9]—Design and Testing of the Heating Equipment, and Method of Measuring Specimen Temperatures

CONSIDERABLE discrepancy seems to exist between the data on the physical properties of metals at elevated temperatures as published by several independent investigators. There are undoubtedly several reasons for this, but from a consideration of the apparatus used as described by some of the investigators who have published data, it seems quite possible that one cause is directly associated with the apparatus used to maintain the specimens at the desired temperature and the method of determining the temperature of the specimen. In some cases the heating equipment is inadequate to produce a uniform temperature throughout the specimen or test part of the specimen being subjected to the test, and in other cases it is doubtful if the temperature of the specimen is correctly measured.

The Technical Direction Bureau of the Aluminum Company of America has conducted a large number of tests to determine the effect of temperature on the tensile properties of aluminum and aluminum alloys, the results of which have been given in the first part of this paper. Before commencing these tests much time and thought was given to the construction of suitable heating equipment, and on testing it to determine the temperature uniformity of the specimen and the accuracy of the measurement of specimen temperatures, and this Part II has been written to substantiate the data presented in the first part of the paper.

Also, since entirely satisfactory results were not obtained with the apparatus originally constructed, a brief description of the preliminary tests and alterations to the apparatus has been included in order that some of the possibilities of adverse conditions may be realized by others.

The original furnace was constructed in the fall of 1923 and was arranged for the use of an oil-bath heating medium for moderate temperatures and a salt-bath medium for higher temperatures. The general arrangement of the furnace and bath container is shown in Fig. 23.

Before the furnace was placed in service it was desired to make certain tests to determine the relation between the specimen temperature and the bath temperature, and the temperature uniformity throughout the specimen.

In order to determine the temperature uniformity throughout

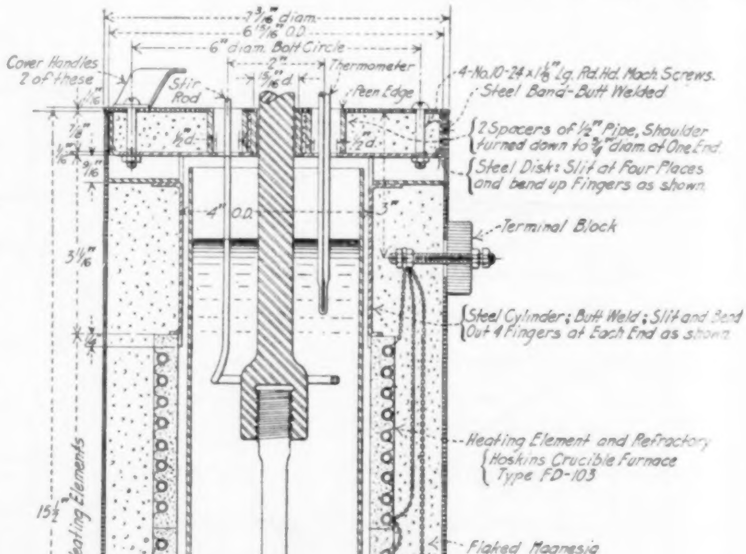

FIG. 23 ASSEMBLY DRAWING OF ORIGINAL FURNACE

[9] By Kirtland Marsh.

the specimen, three thermocouples made up of No. 20 B. & S. gage iron-constantan asbestos-insulated thermoelement wire were inserted in the specimen as shown in Fig. 24(*a*). Three diametrical holes $^1/_8$ in. in diameter were drilled through the specimen, one in each shoulder and one at the center of the reduced section, and in addition three radial holes were drilled perpendicular to them. The asbestos-insulated thermocouples were threaded through these diametrical holes until the hot junction was at the center of the specimen, care being taken to keep the asbestos insulation intact so that it would extend inside the surface of the specimen. In this manner the thermoelements were prevented from touching the specimen except at the hot junction, and they were protected from the higher-temperature atmosphere around the specimen. When the hot junction of each couple was properly centered, a soft aluminum rivet was driven into each radial hole so as to press the hot junctions firmly against the metal of the specimen and thus make good thermal contact with it.

It was felt that with the specimen thermocouples inserted in this manner, the temperature of the hot junction of the thermocouple—which is the temperature actually measured—would agree with the temperature of the center of the specimen at that point to within a small fraction of 1 deg. fahr. The thermoelement wire was of relatively small cross-section and therefore of small mass; the hot junction was small, only sufficient silver solder being used to securely connect the two elements; the asbestos insulation reduced the heat flow from the hotter medium surrounding the specimen to the thermoelement wires, and therefore reduced the conduction of heat along the elements to the hot junctions; good thermal contact between the hot junction of the thermocouple and the specimen was obtained; the asbestos insulation practically sealed the ends of the diametrical hole in the specimen and thereby eliminated any circulation of the heating medium around the hot junction. No actual tests were made to determine how closely the thermocouples measured the temperature of the specimen at the points of insertion, but from a consideration of the methods used and precautions taken, it is believed that any one familiar with

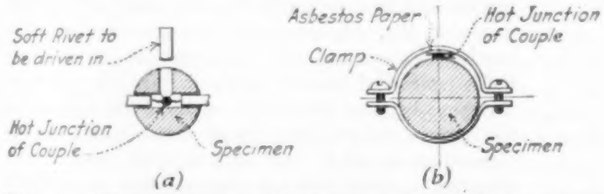

FIG. 24 CROSS-SECTIONS OF SPECIMEN SHOWING (*a*) METHOD OF INSERTING THERMOCOUPLES AND (*b*) METHOD OF CLAMPING THERMOCOUPLE TO SHOULDER OF SPECIMEN

accurate temperature measurements will agree that the temperature of the hot junction and of the specimen probably did not differ by more than a small fraction of 1 deg. fahr.

Previous to these tests the thermoelement wire was calibrated at the freezing points of tin, zinc, and aluminum.

Since it is impossible to drill a hole for a thermocouple at the center of a specimen to be pulled, and impractical to insert thermocouples in the shoulders of each specimen, it was highly desirable that some other means of measuring the specimen temperature be devised. It was decided to clamp a couple against the shoulder of the specimen and compare the temperatures as measured by the clamped-on couple with the temperatures measured by a couple inserted in the same shoulder as described above. A thermocouple was made up of the same thermoelement wire as used for the inserted couples, namely, No. 20 B. & S. gage asbestos-insulated iron-constantan wire. After being soldered, the hot junction was slightly flattened by tapping it lightly with a small hammer. A small band or clamp was made of two pieces of about No. 14 gage sheet steel $^1/_4$ in. wide and held together by two screws. In clamping the couple to the specimen, the hot junction was laid against the specimen and a piece of asbestos paper placed between the steel clamp and the hot junction. Fig. 24(*b*) shows the method of clamping the couple to the specimen.

It was found that the clamped-on couple agreed almost ex-

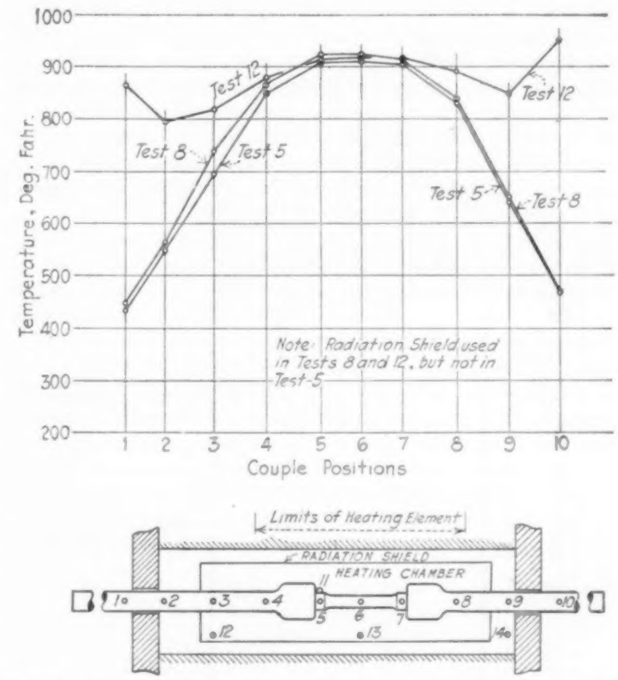

FIG. 25 DIAGRAM OF HEATING EQUIPMENT SHOWING LOCATION OF THERMOCOUPLES AND TEMPERATURE-DISTRIBUTION CURVES FOR TESTS 5, 8, AND 12

actly with the inserted couple, the difference being less than 0.5 deg. fahr. as measured on a precision potentiometer.

The first few tests were made with the specimen heated in air and later in an oil bath. No tests were made with the specimen in a salt bath due to the practical impossibility of protecting the couples from the bath.

Surprisingly good temperature uniformity throughout the specimen was obtained when the specimen was heated in air.

Accordingly, since the use of an oil or salt bath is attended with considerably greater risk to the operator, and the manipulation of the apparatus is considerably more complicated and the fracture is obscured with oil or salt, it was decided to eliminate the use of an oil or salt bath and employ a heating medium of air only. The bath holder with the stuffing box on the bottom end as shown in Fig. 23 was therefore removed.

After this furnace was placed in service, it was soon learned that a specimen pulled at a sufficiently high temperature to give an elongation of 100 to 150 per cent in two inches was subjected to considerable cooling as the top of the specimen was drawn toward the top of the furnace. The reason for this was obvious. In test 5 (see Fig. 25), with a constant specimen temperature of 910 deg. fahr., the temperature of the air surrounding the specimen was about 100 deg. fahr. higher than the specimen temperature. The conduction of heat along the specimen holders was so great that a temperature differential of 100 deg. fahr. between the specimen and the surrounding air was necessary before the heat transfer from the air to the specimen and specimen holders equaled the heat loss through the holders.

The data from test 5, Table 3, show the relation between the temperature of the specimen, holders, and the furnace atmosphere.

It was believed that the temperature at the center of the specimen would be affected as well as the temperature of the top shoulder, and as such a condition would be highly undesirable, particularly since the temperature at the center of the specimen was not measured, it was decided that such alterations to the equipment as were necessary should be made to eliminate these conditions.

A radiation shield consisting of a sheet-iron cylinder with open ends was tried out with the hope of producing a more uniform temperature, but without success as shown by test 8, Fig. 25.

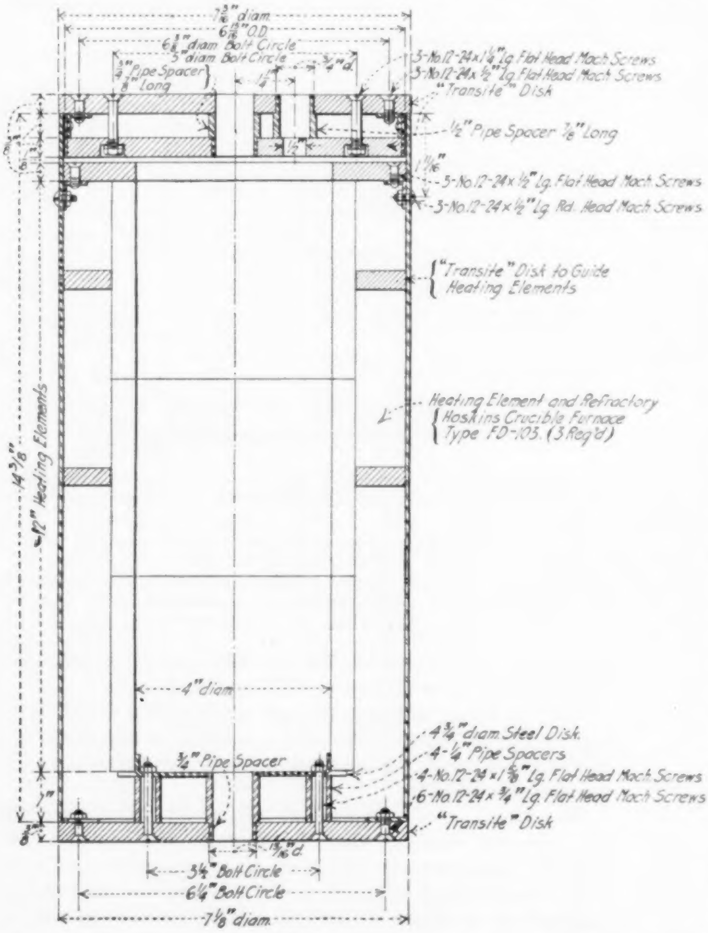

Fig. 26 Drawing Showing Principal Changes to Main Furnace After Test 12

After considerable study it was decided to provide additional heating elements around those parts of the specimen holders that extended beyond the ends of the main furnace in order that the heat conducted along the holders and dissipated into the air and the heads of the testing machine could be absorbed from the additional heating elements, or "end heaters" as they were subsequently termed, instead of being drawn from the specimen and the atmosphere surrounding those parts of the holders in the main furnace. For this purpose two Type 70-3 multiple-unit electric furnaces with a rating of 2.3 amperes on 220 volts were obtained and placed around the holders at the end of the main furnace.

No assembly drawing or photograph of the main furnace as originally constructed or with the end heaters is available, but the external appearance is practically the same as shown in the photograph of the final arrangement, Fig. 4.

Subsequent to the addition of the end heaters, further tests were made using the three inserted couples and the one clamped-on couple for measuring the specimen temperatures, together with several additional couples to measure the temperature of the holders and the furnace atmosphere. The couples in the holders were made up in the same manner as the couples inserted in the specimen, and were inserted in the holders in the same manner except that No. 6 iron machine screws instead of rivets were used to press the hot junctions against the interior of the holders.

These tests, of which test 12 (see Fig. 25) is typical, showed that conditions had been considerably improved but that there was still a considerable drop in temperature along the specimen holders between the ends of the specimen and the ends of the main furnace, even though the temperature of those parts of the holders in the end heaters was nearly up to the specimen temperature. This was attributed in part to the fact that the heating elements in the main furnace extended over a length of only 8 in., whereas the heating chamber was $13^1/_2$ in. long, with the result that there was considerable length between the ends of these heating elements and those in the end heaters. The main furnace was then reconstructed; the principal changes, shown in Fig. 26, consisted of spreading the same heating element out over the length of three refractories instead of two as shown in Fig. 23, reducing the space between the bottom of the cover and top of the furnace, and replacing the sheet-steel tops and bottoms of cover and furnace with asbestos board. The specimen couples were not changed, but those in the holders were relocated and additional couples inserted.

Fig. 27 shows diagrammatically the arrangement of the two end heaters and the main furnace, as well as the relocation of the thermocouples in the specimen and holders.

The addition of the end heaters increased the amount of control equipment required, and in order to facilitate the operation of the furnace, a control board was designed and constructed. Fig. 28 shows the wiring diagram of this control board, and indicates the apparatus mounted thereon.

TABLE 3 DATA FROM TEMPERATURE-DISTRIBUTION TESTS

(a) Clamped-on couple short-circuited in this test.

The heating element in the main furnace was divided into two sections, so arranged that they could be connected in series or parallel. The two end heaters were also arranged so that they

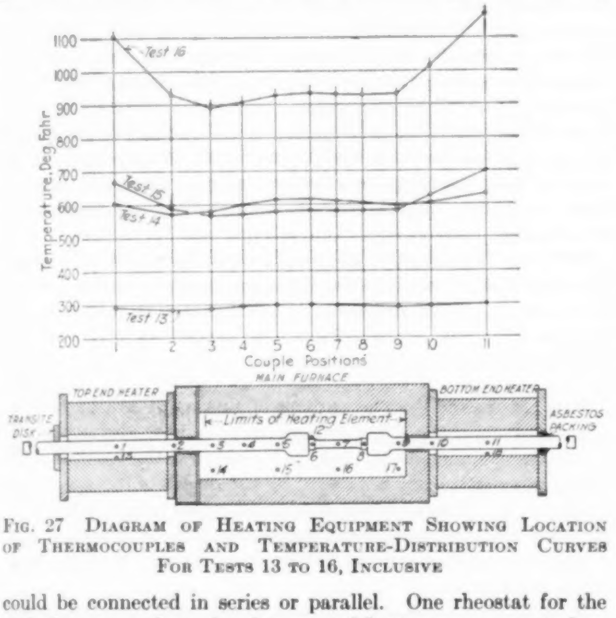

FIG. 27 DIAGRAM OF HEATING EQUIPMENT SHOWING LOCATION OF THERMOCOUPLES AND TEMPERATURE-DISTRIBUTION CURVES FOR TESTS 13 TO 16, INCLUSIVE

could be connected in series or parallel. One rheostat for the main furnace and one for the two end heaters were mounted on the board.

Following the last-mentioned changes to the furnace and the construction of the control board, further tests were made. The current through the main furnace was adjusted to give the desired specimen temperature, but the current through the end heaters was adjusted to produce and maintain different conditions in an effort to determine which method of control would produce the most uniform temperature throughout the length of specimen and those parts of the holders in the main furnace. During the first test of this series, No. 13, the current through the end heaters was adjusted to make the temperature of the specimen holders in the end heaters as measured by couples 1 and 11 (see curve sheet, Fig. 27) agree with the specimen temperature of 296 deg. fahr., couple No. 7. However, it was found that the temperature of No. 1 couple was above and that of No. 11 couple below the specimen temperature, and accordingly since only one of these could be made to agree with the specimen temperature, test 14 was run with the current through the end heaters adjusted to make couple No. 1 agree with the specimen temperature of 610 deg. fahr. As can be seen from the curve for test 14 (Fig. 27), there was considerable drop in temperature along that part of the specimen holder within the main furnace from the specimen end toward the end of the main furnace, and the differential throughout the specimen was 12 deg. fahr. It was decided that it would be more desirable to have a more uniform temperature along those parts of the holders in the main furnace, and accordingly in test 15 (Fig. 27) the current through the end heaters was controlled to make the temperature at couple No. 9 agree with the specimen temperature, couple No. 7. The maximum temperature differential between the three couples inserted in the specimen was only 2 deg. fahr., while the maximum differential throughout the specimen and that part of the holders within the main furnace was only 15 deg. fahr.

Test 16, Fig. 27, was a repetition of test 15, but with a specimen temperature of 900 deg. fahr. The temperature differential throughout the specimen was 6 deg. fahr., and throughout the specimen and those parts of the holders within the main furnace was 42 deg. fahr.

One set of readings from each test referred to, taken after temperature equilibrium had been reached, is given in Table 3.

After careful consideration it was decided that the best method of operating the furnace would be to regulate the current through the end heaters to make couple 9 agree with couple 7, or since couple 7 could not be used when the specimen was being pulled, to make No. 9 agree with the average of the temperatures as measured by couples clamped to the top and bottom shoulder of the specimen.

A comparison of the temperatures as measured by couple No. 6 which was inserted in the top shoulder of the specimen and by couple No. 12 which was clamped to the top shoulder of the specimen, shows that the clamped-on couple can be relied upon to measure the temperature of the specimen. The addition of the end heaters and reconstruction of the main furnace reduced the temperature differential between the specimen and the surrounding air from 115 deg. fahr., to less than 20 deg. fahr. This condition would tend to make the clamped-on couples more reliable, since no part of the couple near the hot junction is exposed to a temperature very much greater or less than the temperature of the hot junction.

The results of tests 13, 15, and 16 indicate that for specimen temperatures as high as 925 deg. fahr. a temperature differential throughout the specimen not to exceed 6 deg. fahr. may be expected, and that the temperature of the top end of the specimen should not drop appreciably as it is being pulled, even when the specimen temperature is such as to produce large elongations.

During the actual pulling of specimens, only a relatively few couples can be used, and after due consideration it was decided to use one couple in each of the end heaters and the main furnace

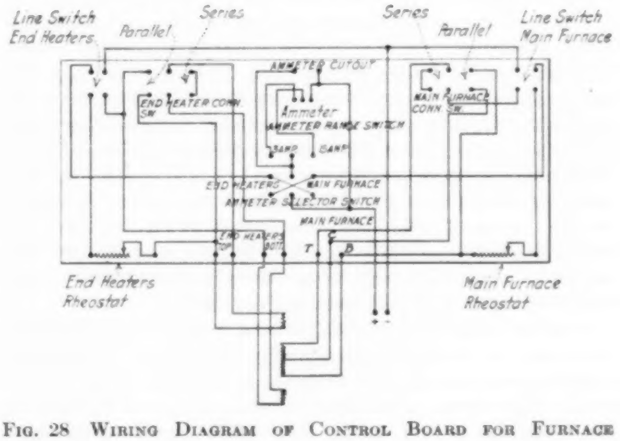

FIG. 28 WIRING DIAGRAM OF CONTROL BOARD FOR FURNACE

to measure the atmospheric temperatures. In addition to these furnace couples, a couple was inserted in the bottom holder in the same position as couple 9 in tests 13 to 16. Since the bottom holder did not have to be removed to insert or remove a specimen, a couple could be permanently mounted in the bottom holder without interfering with the operation of the equipment. Two couples to be clamped to the top and bottom shoulders of each specimen pulled were also provided.

The cold junctions of all six thermocouples were inserted in a thermos bottle, and all couples were connected to a sensitive indicating deflection-type pyrometer by means of a selector switch. In addition to the indicating pyrometer, a recording pyrometer was connected to the couple in the bottom holder and the two clamped-on couples; this not only provided a permanent record of the pertinent temperatures, but showed the trend of the temperature curves and enabled the operator to better adjust the rheostats.

During tests 14 to 16, a record was kept of the current required

through the main furnace and through the end heaters to produce the desired conditions at the several different temperatures, and from the data obtained, curves were drawn to show the current required in both circuits to maintain any desired specimen temperature. These curves, although not satisfactory for the final adjustment of the rheostats, enable the operator to adjust the rheostats approximately correctly without undue hunting.

The complete equipment, consisting of the furnace, control board, and pyrometric equipment, was set up and turned over to the laboratory with the following recommendations:

> After the specimen is mounted in the furnace, the temperature of the specimen should be brought to the desired temperature as closely and quickly as possible, and with as little hunting as possible. The temperature of the couple in the bottom holder should be made to agree with the temperature of the specimen to within ±3 deg. fahr. The specimen should be allowed to remain at temperature equilibrium for at least 20 minutes before the pull is started. Temperature equilibrium is defined as a rate of change in temperature of less than 2 deg. fahr. in 10 minutes or 12 deg. per hour. The temperature of the top and bottom shoulders of the specimen and the temperature of the bottom holder as shown by the indicating pyrometer at the beginning and end of the pull should be recorded.

The relatively fine-gage iron-constantan couples used in this equipment, the same as those used in the tests, are not satisfactory for long use, but the thermoelement wire is relatively inexpensive, even with the asbestos insulation, and it is a simple matter to make up new couples and install them.

The bureau staff believe that they are measuring the temperature of each specimen pulled with an accuracy of at least ±1.0 per cent, and that the maximum temperature differential throughout the specimen during routine tests does not exceed 10 deg. fahr.

The apparatus as described above was designed and used for the testing of aluminum and aluminum alloys which have a high coefficient of conductivity for heat. The high conductivity was undoubtedly of considerable advantage and instrumental in securing a low temperature differential throughout the specimen. Table 229 on page 213 of the Smithsonian Physical Tables, 7th revised edition, gives the coefficient of conductivity for aluminum at 18 deg. cent. as 0.514, and for 1 per cent carbon steel at 18 deg. cent. as 0.108. The bureau staff would not expect to obtain as good results with steel in this furnace as they do with aluminum, and considerable further alteration might be necessary to produce equitable results with steel specimens.

A similar investigation of all furnaces used for this purpose to determine the temperature uniformity throughout the specimen and the accuracy of measurement of specimen temperatures would do much to substantiate the data obtained by independent investigators and make their data much more comparable.

Acknowledgment is made to Mr. J. K. Miller, Jr., for his assistance in conducting the many preliminary and final tests of this apparatus.

## Discussion

J. M. Lessells.[10] The method described in this paper of measuring elastic extensions is novel, but experience indicates that it would not be suitable for materials like steel with higher modulus values. This of course has been realized by Mr. Templin, and he has made remarks accordingly. This point, however, is worthy of emphasis.

A further point of interest is in Fig. 6. The writer would suggest that the authors include the temperatures on the curves, because the curve for 200 deg. fahr. has not been shown.

[10] Engineer in Charge of Mechanics Section, Research Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

The "kink" in the tensile and yield-point curves for alloy 112 as cast and for alloys 195 and 196 as heat-treated are interesting. Mr. Templin comments on the fact that such phenomena have been observed by other investigators but have not been explained, yet he does not explain these peculiarities himself. It would be very interesting to have more comments on this phase of the work because it should be noted that the alloys giving these peculiarities are all high in copper. Possibly the phenomena are due to release of residual stresses, due to structural changes during the aging process, and one would expect great changes in the form of the tensile-test diagram after this aging. It should also be noted that alloy 122, also high in copper, does not show these peculiarities, therefore such cannot be due to copper alone.

With the fine furnace equipment used in these tests it is to be regretted that the results of duplicate tests were not given. Mention is made by the authors of the fact that this variation was ± 4 per cent, but it would have been interesting to see all the values plotted.

P. G. McVetty.[11] The authors of this paper are to be congratulated upon the manner in which they have developed the apparatus, conducted the tests, and presented the results. The writer was particularly impressed by the details of furnace design given by Mr. Marsh. The use of end heaters to reduce the temperature gradients within the furnace is undoubtedly an excellent method of securing a more uniform temperature in all parts of the test specimen.

We also have found that a thermocouple held firmly against the surface of the specimen gives fairly satisfactory results.[12]

Mr. Marsh has mentioned the fact that the high thermal conductivity of the aluminum alloys tested has helped to decrease the temperature differential throughout the specimen. This emphasizes a point which is often neglected, namely, that the same furnace is not equally satisfactory for all materials.

There is one other factor that the writer would like to mention and that is the part played by the low modulus of elasticity of aluminum alloys in making the results more consistent. This modulus is very low at the higher temperatures, and as a result the deformation for a given change in stress is large. On this account the changes in length due to temperature fluctuations become relatively unimportant. If the same apparatus which has been described were used in testing alloy steels of the type adapted to high-temperature service, it would be found desirable to hold the temperature during the test within even closer limits. We have found that the results are much more affected by temperature fluctuations during the test than they are by small temperature gradients within the specimen.

The writer agrees heartily with Mr. Marsh that a similar study of the furnaces used by different investigators would aid materially in explaining the discrepancies found in comparing results obtained by different laboratories.

O. W. Ellis.[13] The authors have called attention to the speed of testing, particularly in the case of those alloys which can be age-hardened. The test samples, according to the paper, were in all cases kept at the required testing temperature for 30 min., and were then stressed to the point of failure, the speed of testing being 0.107 in. per min. The writer would be interested to know if any tests were made in which the test sample was kept for a longer time than 30 min. at the testing temperature or in which

[13] Research Dept. Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

the test sample was pulled at slower speeds. The following possibilities come to mind: (1) The complete precipitation of solute compounds during a longer period of time than 30 min. prior to test, or (2) the complete precipitation of such compounds during the actual testing operation; this, however, occupying a longer period of time than usual, owing to the use of a testing speed of less than 0.107 in. per min. The question arises, what would be the effect of such precipitation prior to or during the test on the test result? It seems likely that as a result of the complete precipitation of the solute constituents prior to or during test, certain of the kinks which characterize the curves of the heat-treated alloys would be completely ironed out.

Mr. Archer, of the Aluminum Company of America, while discussing with the writer the possibility of using certain aluminum alloys as bearing metals, referred to a fact which is of considerable interest in this discussion, i.e., that aluminum bearings tend to seize on steel shafts very readily. He offered as an explanation of this phenomenon the relatively high affinity of aluminum and iron, an affinity which is considerably greater than that of iron for either tin or lead. Recently a paper was presented at one of the meetings of the Royal Society (Proc. Roy. Soc., 1927, 115 (A), 472) in which the rapid rusting both of lubricated and unlubricated steel parts in firm and close contact and moving slightly relative to one another was discussed and explained. In this paper Tomlinson, the author, says:

"The most probable explanation of the effect which suggests itself is that it is a result of molecular cohesion. When two solids touch, the forces between the molecules or at least some of the molecules are sufficiently high to cause the molecule to be detached by a lateral movement. It seems certain that the force between two molecules which approach and recede normally is definitely smaller than the forces holding either molecule to the solid. Experiment E in which the relative motion is always exactly normal to both surfaces shows this, and all experience with ball bearings proves that the rusting effect does not occur with pure rolling. The nature of the bonds between the molecules appears to be such that the cohesive force of a visiting molecule is quite insufficient to pluck the molecule out normally, but is sufficient to detach it from the solid when applied tangentially. This suggests the view that the boundary molecules, by virtue of their unsymmetrical position, have a considerable degree of orientation, so that an external tangential force is able to disturb the initial equilibrium so much that individual molecules as distinct from finite particles can be wrenched away. To use a crude analogy, a tooth is more easily uprooted by a side pull than by a normal pull. The molecules so detached combine very quickly with oxygen molecules from the atmosphere."

Stress is here laid on the ready combination of the detached molecules of iron with the oxygen of the atmosphere. When contact is made, as in bearings, between steel and aluminum, which is of all the commoner metals that most readily oxidized, the formation of a large amount of aluminum oxide can, under certain conditions of service, readily occur. On the one hand is the fact that there exists a film of oxide on the metal to start with; on the other, the possibility that relative movement could increase the amount of this oxide in the manner hinted at by Tomlinson. The speaker therefore is of the opinion that the affinity of aluminum for iron per se cannot account for the ready seizure of the two metals as in bearings, but that the affinity of aluminum for oxygen must be considered as of equal importance in determining bearing failures in which aluminum alloys play a part. There is no reason, however, why these alloys should not sooner or later be used in this connection. We have to find out how to use them on the one hand and where to use them on the other.

F. M. Brauer.[14] Three or four months ago, the Ordnance Department found a metal that was light, yet with physical properties that would permit its use in mobile anti-aircraft mounts. After spending considerable time in investigations, analyzing numerous tests, and consulting engineers and other experts, a metal having specifications known as No. 195, heat treatment No. 4, was found, which with but a few modifications would be adaptable. Six per cent elongation, 13,000-lb. per sq. in. yield point with 28,000-lb. per sq. in. ultimate, was established. Further than that an order was placed for this metal to be used in very important components of gun carriages. It may appear singular that the department should introduce a metal of this kind and put it into a gun carriage; however, there was no hesitancy in so doing, and we are firmly convinced that not only these components, but that in the near future other parts, will be changed over from cast steel having a 30,000-lb. yield point and 70,000-lb. ultimate, to aluminum-alloy casting No. 195.

Not only are the specifications as to physical properties carefully checked, but also an actual test is made and each member subjected to a load equal to that which will produce a fiber stress of 80 per cent of the strength of the metal at the yield point.

A. W. France.[15] The writer would be interested to know if any experiments have been conducted on aluminum alloys for possible use as piston or packing rings at high temperatures where copper alloys and cast iron no longer serve satisfactorily.

# Sheet Rolling

By LEON CAMMEN,[1] NEW YORK, N. Y.

*In this paper, after distinguishing between strip and sheet, and between hot and cold rolling, the author points out that mills are today rolling to surface specifications which would have been considered impossible five years ago, and that barring certain contingencies, stricter specifications may prevail in the near future. In the course of his treatment of the subject he describes the continuous process of sheet rolling, temperature and labor, roll life, engineering economies of the sheet-rolling business, rolling with heating between passes, sheet rolling in Germany, sheet and roughing mills of the future, the price problem, etc. In the author's opinion the economic side of the industry will have to be reorganized along lines which have proved successful throughout the entire American industry; and this will be in the direction of reduction of the number of plants and concentration of output in larger and better-equipped units capable of meeting the strenuous specifications of today in an economical manner and by those knowing enough about their costs to demand a fair price for their products.*

IT IS COMMON to speak of industries as if they were living beings. Thus, we hear of the birthday of an industry, its silver anniversary, and the like. The art of sheet rolling is said to have originated in England in 1728. This would give this art an age of over two hundred years. An analysis of its present development would give it a mentality of twelve years as applied to steel, and probably around eight or nine years as applied to copper and brass.

## Sheet and Strip

In the rolling of sheets several distinctions are made which it is well to understand from the beginning. In the first place, a distinction is made between sheet rolling as such and strip rolling. The difference lies in the fact that in sheet rolling proper pieces of comparatively small lengths are produced, not in excess of 20 ft. as a rule, and usually varying from 96 to 144 in. In strip rolling very long pieces, up to 2000 ft. or even longer, are produced. A further distinction which held good formerly was that strip was supposed to be rolled in comparatively limited widths and varied from what is known as flat wire, say, $^1/_4$ in. wide, up to about 24 in. in width. Sheet was rolled from that width up to 48 in. as a regular commercial product, and 64 in. as specialties. This distinction has been largely done away with by the recent development of so-called wide-strip rolling by which sheet is produced today in widths up to 42 in. and could be produced in greater widths if commercial requirements could justify the very large expenditure involved. Technically, therefore, the difference between strip and sheet in the matter of width may be considered to be completely done away with.

## "Hot" and "Cold" Rolling

The next distinction made is between hot and cold rolling. This is a very important distinction, which makes it all the more unfortunate that the terms are entirely misunderstood in the trade. As improperly used today, rolling at temperatures in excess of, say, 1000 deg. fahr., is described as hot rolling, while by cold rolling is understood rolling where the metal entering the rolls is at a temperature somewhere between 100 and 200 deg. fahr. This is, however, an entirely improper description, and, for example, C. B. Francis and J. M. Kemp ("Making, Shaping, and Treating of Steel," 4th edition, p. 959) show that all rolling below the critical point (1290 deg. fahr. for the usual low-carbon steel) is cold rolling. This not only follows from the definition of hot rolling but is shown by the result. Steel rolled above the critical temperature, as, for example, in rail manufacture, when finished is strong and lacks the brittle hardness induced by cold working. It can therefore be subjected to its usual service stresses, among them shock stresses, without annealing. On the other hand, the so-called hot-rolled sheet as it finally comes out of the rolls has the coarse, elongated-crystal structure and brittle hardness distinguishing cold-rolled products and cannot be used for shaping or drawing without a preliminary anneal.

## Surface Specifications

A further distinction must be made, and that is between sheet specified to show a good surface and sheet where only the drawing qualities, strength, or the like, have to be produced. In a way, as will be shown later, there is no reason why all sheet should not be rolled to a good, clean surface. Actually, however, the requirements of modern specifications for certain classes of goods as regards surface are so stringent that the most elaborate precautions have to be taken to produce the desired kind of surface. Suffice it to mention as an illustration that a case is known where sheet was disqualified as to surface conditions because the roller inadvertently dropped a bit of cigarette ash while the piece was going through the rolls. The modern methods of painting, particularly as applied to such products as steel furniture and automobile bodies, are also such as to bring out the slightest defect in surface conditions. The result of this is that mills are rolling today to surface specifications which would have been considered absolutely impossible only five years ago, and all indications are that, unless new methods of painting and japanning are discovered, even stricter specifications than prevail today will be insisted upon and most likely obtained by the large purchasers.

There is still another distinction, namely that between sheets on which the manufacturer makes profit and those on which he loses money. But this, like the matter of one's religion, is a subject which can be discussed only between the maker of the sheets and his stockholders.

## Conventional Sheet Rolling

In the rolling of ordinary sheets (i.e., not strip sheets) of plain carbon steel (which means between 0.06 and 0.12 per cent), the customary cycle of rolling is as follows: A sheet bar is selected such that the length is equal to or slightly in excess of the width of the finished sheet. The width is usually 8 in., although 12-in. bars are sometimes used. The thickness of sheet bar is such as to give the necessary weight of the sheet, and usually varies from about 0.75 to 1.25 in., although of course lighter and heavier sheet bars are used for specialties. The sheet bars are heated to the selected rolling temperature, which may vary from 1550 to 1750 deg. fahr., in what is known as a "pair" furnace, so called because the sheet bars are taken out of it in pairs. When the bars have reached the proper temperature, the control of which is in charge of the heater, a pair of them are taken out by an attendant and dragged over by tongs to the roughing mill. The roughing mill is attended by two men, the roller and catcher. The former grabs one of the bars by tongs and feeds it into the mill. The catcher, standing on the other side, catches the piece and lifts it to the top of the roll, with the result that it rolls back to the roller. In the meantime the roller passes the second

[1] Consulting Engineer.

bar of the pair into the mill, so that for a while pieces of hot metal travel one through the rolls from the roller to the catcher and another over the top roll from the catcher to the roller. All of this is done with great rapidity, which is necessary in order to get as much rough rolling done as possible before the pieces become too cold, and requires great skill as well as strength, muscular endurance, and ability to withstand conditions which would lead to pulmonary and blood circulatory diseases in any one but those physically qualified for this kind of work. A combination of all these qualifications, together with the desire to do heavy muscular work, is not common in American labor and has to be paid for accordingly. While therefore the roughing mill is a cheap and simple piece of apparatus showing a comparatively low consumption of that kind of power which can be expressed in terms of pounds of steam or kilowatts per hour, the process of rolling is anything but cheap. This comes, however, under the relation of man power to mechanical power in sheet rolling, and will be discussed more fully elsewhere.

Practice in sheet rolling is not uniform throughout the country. In some plants roughing is continued only as long as it can be done with the original heat of the sheet bar; in others, the semi-rough sheet is reheated and returned to the roughing mill. The

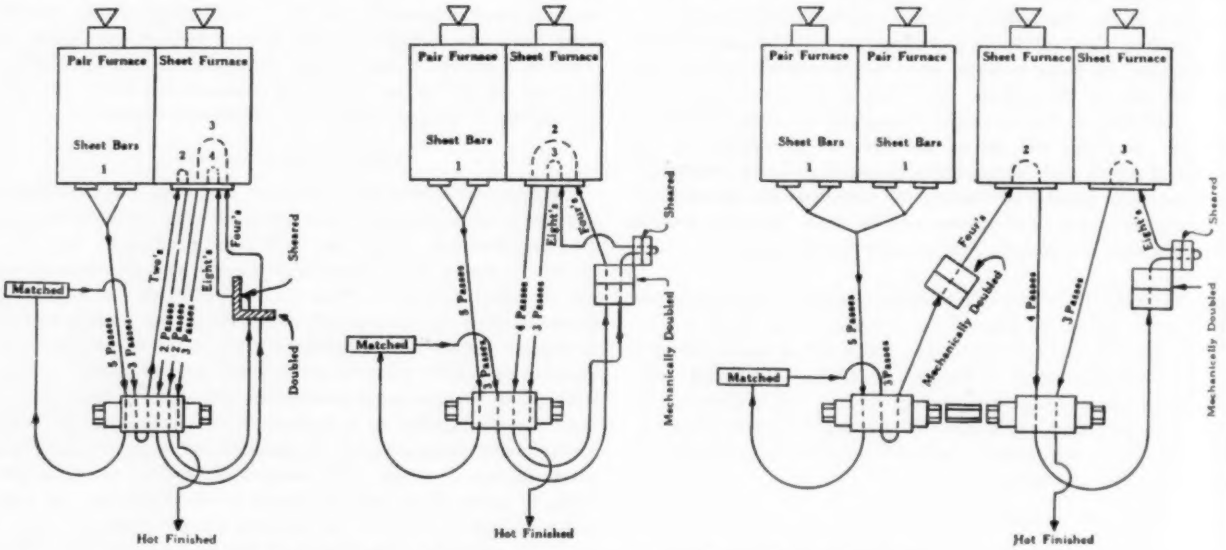

FIG. 1 THREE METHODS OF ROLLING BLACK PLATE FROM SHEET BARS

1 Various steps involved in rolling black plate from the heating of the pairs to the finishing of the pack as conducted by the majority of tinplate producers on a single mill by the four-part system. Thirteen distinct operations are entailed.
2 The installation of a mechanical doubling machine alleviates the laborious work associated with the folding operation and affords increased production by the elimination of one heating.
3 By doubling the equipment and operating two mills as a unit on the three-part system, larger tonnages can be handled than by working two mills singly on the four-part system and considerable backtracking is eliminated.

general tendency is to roll the sheet to about twice its desired thickness in the roughing mill. There is a limit to which sheet can be rolled singly. The permissible variation in thickness from standard gage is usually $\pm$ $2^1/_2$ per cent, which in the thinner gages amounts to only a couple of thousandths of an inch.

If it is considered that the expansion of the rolls may easily exceed this amount, it will become obvious why single sheets cannot be rolled to their final thickness, provided this is less than, say, 14 or 16 gage.

From the roughing mill the sheet goes to the doubler or matcher. The doubler is a device which folds the sheet in the same way as a piece of paper may be folded double. The introduction of the mechanical doubler some six or seven years ago was one of the most important advances in sheet-mill engineering and has produced a material savings in cost of operation. The usual method is to double the sheet and then put two or three of the doubled sheets together into a pack. The mechanical doubler is usually combined with a very simple device known as a mechanical matcher. The matched pack goes to the finishing mill where it may be rolled to the gage required. Two diagrams, Figs. 1 to 6 illustrate the various methods of rolling as determined by the use, or lack, of the mechanical doubler and by the use, or lack, of a separate sheet furnace as differing from the pair furnace, the former being then used only for the reheating of material rolled in the finishing mill, while the pair furnace retains its primary function of serving the roughing mill.

### Temperature and Labor in Sheet Rolling

A very significant light is thrown on the modern sheet industry by Table 1, which states the crews required under the various systems. The production in the United States varies from seven tons or less to fifteen tons per turn of 8 hours, or substantially around one ton per man in 8 hours. This saddles sheet making with a labor cost varying with various plants and various finishes and gage thicknesses but roughly of from $5.50 to $6 per ton of 22-gage sheets, which is more than ten times as high as is the case with any other rolled-steel product.

From the above certain significant conclusions can be drawn. In the first place, apart from the question of furnaces—which are becoming more and more expensive—sheet-rolling-mill equipment on the face of it is remarkably cheap. Where a rolling unit for any other product runs into seven figures, a sheet mill can be put up for less than $250,000. This is true, however, only if we accept the figures uncritically, because the sheet mill, unlike any other metal mills in American practice, has no mechanical manipulators and is operated throughout by manual power, although driven, of course, by mechanical power. To be fair, therefore, "first cost" of the rollers and catchers should be added to the cost of the sheet mill at the very least. The cost of a skilled workman in America is estimated at between $50,000 and $75,000, and the addition indicated will change completely the mill cost.

Moreover, American manufacturing conditions are such as to make the employment of manual labor basically uneconomical wherever it can be replaced by mechanical labor. Throughout the industry shovels, trucks, conveyors, manipulators, cranes, trench diggers, loggers, etc., have replaced man power. Bottles

One pack of 8 sheets double length.)

are no longer blown by lung power, but are produced by the million by machinery. Cement sacks are also filled mechanically, and even in the sheet industry the automatic doubler and matcher has brought about a little revolution in methods of production. However, when it comes to rolling, exactly the same methods prevail as were introduced by the first Welsh mill men.

The use of muscular power instead of mechanical manipulators reflects on the industry in two ways: In the first place, the roller and catcher have to combine high-grade skill and judgment with a powerful physique, a combination by no means common, and therefore expensive.

In the second place, the roll speeds have to be proportioned not with regard to the best rolling conditions but with regard to the ability of the catcher and roller to handle the pieces. The standard speed for 28-in. rolls may be set at 30 r.p.m., which is entirely too low for economical production. Any

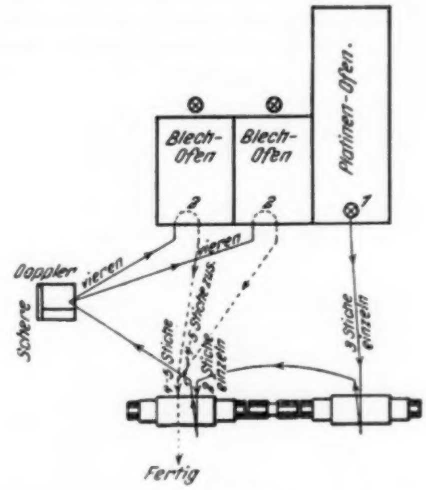

Fig. 3 German Double Mill for Two-Heat Process. Sheets 39.37 × 78.74 × 0.019 In. Sheet Bars 9.84 × 0.374 In., Rolled in Pairs

(Sequence of operations: 1, heating the sheet bars; 2, roughing, 3 passes each; 3, rolling on finishing stand, 2 passes each singly; 4, four or five passes sheets piled; 5, doubling and cutting; 6, reheating in fours; 7, finishing 4 or 5 passes. One pack of 4 sheets single length.)

higher speed of the rolls, however, would discharge the sheet with such energy as to make it difficult for the catcher to take it and would throw back the sheet to the roller at a speed that would make it dangerous for the latter. It is therefore the human factor and not mechanical considerations that governs rolling speed and hence mill output, and that is not a reasonable or desirable base upon which to plan operations today.

There is another angle to this question which also has to do with output. Because of the fact that sheet in rolling cools very rapidly the rolling is done in a tremendous rush, the roller and the catcher trying their best to reduce its thickness as much as possible before the sheet becomes too cold for further rolling. If we consider that a sheet bar may weigh from 75 to 125 lb. and the pack from two to three times as much, an idea will be gained of the exhausting character of handling such weights at topmost speed under conditions requiring strained attention and at a high surrounding temperature. The result is that probably not more than one-third of the time is actually devoted to rolling, and it may be added that it is a high testimony to the caliber of the men employed in sheet rolling that they can keep going at that rate day in and day out without breaking down or producing sloppy work.

### Roll Life

Now, what happens to the rolls while the men are resting? This is a question which has been seldom asked, not because it is difficult to answer, but because of the fact that the men have to rest has been accepted as a kind of natural condition along with weather, death, and taxes. When the rolls are working, heat is given up to them by the sheets. The temperature of the sheets may vary from about 1500 down to about 1100 deg. fahr. The temperature of the rolls is not supposed to go beyond 700 deg. and is preferably kept at about 600 deg. fahr. Now, when rolling is discontinued the rolls immediately began to lose heat by radia-

tion and conduction, which has two results. In the first place, since conduction losses and, in part, radiation losses occur more rapidly near the ends than in the middle, there is produced immediately a deformation in the shape of the rolls known as "bellying." Every sheet roller is gravely concerned over this factor, but does not generally realize that much of the trouble could be eliminated if the rolling were carried out at such a rate as to maintain a stationary condition of deformation rather than

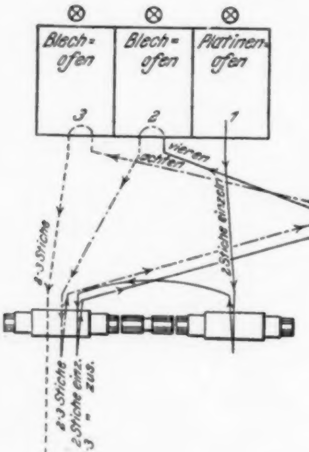

Fig. 4 German Double Mill for New Three-Heat Process. Tinplate 20.87 × 29.92 × 0.0126 In. From Sheet Bars 9.84 × 0.366 In., Rolled in Pairs

(Sequence of operations: 1, heating the sheet bars; 2, roughing, 2 passes; 3, rolling on finishing stand, 2 passes singly; 4, rolling together, 2 or 3 passes; 5, doubling; 6, reheating in fours; 7, rolling, 2 or 3 passes; 8, doubling and cutting; 9, reheating in eights; 10, finishing, 2 or 3 passes. One pack of 8 sheets double length.)

for the roll to swell out and approach again the cylindrical form many times during the turn.

In the next place it ought to be realized in this connection that a roll 30 in. in diameter and anywhere from 26 to 50 in. long contains a tremendous amount of metal. The cooling proceeds from the outside, while the inside is capable of maintaining its temperature for hours at a time. The result is that the inside retains its form and when the outside layer cools it produces a compression with respect to the inside mass and hence a tension in the outside layer itself. This condition is all the more dangerous in the case of hard rolls, as in addition to the contraction stresses produced in the outer layer, the difference in the coefficient of heat contraction between the hard layer and the soft core becomes operative. It is not difficult to realize what happens when the men cease recuperating and start rolling again. The outer layer, which is already in a state of strain, is suddenly subjected to a violent shock by the sheet going into the rolls. The results of this purely unreasonable condition show up prominently in the graph of the expense sheet called "roll maintenance," and most of the defacement of sheet surface is probably due also to the fact that small cracks may exist on the face of the roll for a long time before they become sufficiently prominent to warrant sending the roll back to the machine shop.

### More About Temperature and Labor

Because of the enormous cost of labor per ton in sheet rolling as compared with that of any other steel product, it is not surprising to find that the question of conservation of labor influences the entire structure of the art. The vital element of temperature of rolling is most closely affected thereby. In rolling rails, structural material, etc., an effort is made to carry on the operation through a comparatively narrow range of temperature and finish the rolling while the steel is still above the critical point, the result being that substantially the same grain structure is produced. In sheet rolling, however, it is economically impractical today to follow the same method. Rolling is therefore begun at a temperature several hundred degrees above the critical and carried on to one several hundred degrees below. As a consequence the material passes through the critical temperature at some time during the period of rolling, with the result that an uncertain conglomeration of crystal structures is produced and the material is weak and has to be annealed in order to impart to it the proper physical characteristics.

Furthermore, because of the desire to roll as much as possible between reheats, the initial temperature to which the metal is heated either in the pair furnace or in the sheet furnace is considerably higher than is actually required by the process of rolling. This tends to produce scale, and, where pack rolling is resorted to, to reduce the inner sheets more than is necessary as compared with the outer sheets.

There is yet another economical feature of the present method of sheet rolling which deserves close consideration and is a direct outcome of the fact that muscular labor and not mechanical devices actually control the art. It is significant and only natural economically that as the cost of initial equipment increases, the number of producers decreases and the prices become stabilized. The rail mill is probably the most expensive piece of machinery from the point of view of initial cost, and there are only three companies in the United States making heavy rails. Structural steels require somewhat less expensive equipment, and more companies are producing them. When we come to sheet rolling, we are striking approximately the same economic

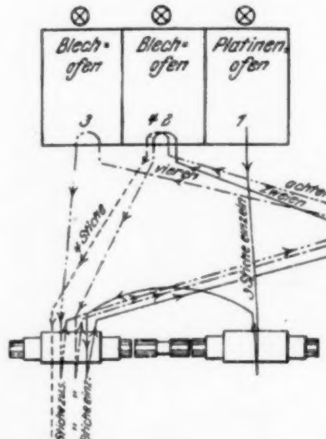

Fig. 5 German Double Mill for New Four-Heat Process. Sheets 20.87 × 29.92 × 0.0079 In. From Sheet Bars 9.84 × 0.472 In., Rolled in Pairs

(Sequence of operations: 1, heating the sheet bars; 2, roughing, 3 passes each; 3, rolling on finishing stand, 2 passes singly; 4, doubling each sheet separately; 5, reheating in pairs; 6, rolling, 4 or 5 passes; 7, doubling and cutting; 8, reheating in fours; 9, rolling 4 to 5 passes; 10, doubling and cutting; 11, reheating in eights; 12, finishing, 2 or 3 passes. One pack of eight sheets double length.)

situation as prevails in, say, ladies' dress manufacture. The initial investment of the plant is small, while the labor costs constitute the essential part of the total cost and do not vary much with the volume of production. It is because of this that in the dry-goods industry small establishments spring up all the time and to a large extent control the level of prices.

### Engineering Economics of the Sheet Business

In sheet rolling as constituted at present the costs for the same class of products are substantially the same in the smallest and the largest plant, while the investment required is so moderate that practically any experienced man with a little money can start making sheets. The small producers as a rule can work cheaper than the large ones, because the owner or the principal stockholders of a small mill are as a rule also its managers and consider the return on their investment largely in the way of salary, while the large mill is managed through hired executives and must make a salary return in addition to a return on stocks. Moreover, the small mill is hungry for business and often willing to work for a lower return. If we add to this that the small mill often does not know its own costs, it will become obvious why it can take away business from the big mill on a price basis and is apt to establish a general level of prices which would not be accepted in industries controlled by big units. It is because of this that except in a very few cases the sheet business has not contributed the share of profits that would be warranted by the volume of its output. In other words, the smaller sheet mills have been willing to do business on other bases than that of profits, and the big mills have had to follow the small mills because there was nothing else to do. It would appear from this that the economic salvation of the sheet industry lies in a complete reorganization of its method of production along such lines as have proved successful throughout the entire American industry, and this means adopting methods of production controlled by the following general principles:

*a* The workman must only control the manufacturing machinery and not operate it by muscular force.

*b* The consumption of labor per unit should be small and the consumption of power should compensate for the reduced consumption of labor.

*c* The first cost of the machinery may be high and the wages should be high, but the labor cost per unit of output should be low.

*d* The operation must be such as to provide automatically for the control of elements which are not of such a character as to require at all times personal control by the operator.

It is significant that throughout the steel industry these principles have been closely followed and have helped American industry in general to attain its dominant position in the world and produce, elsewhere than in the sheet industry, the comparatively large profits of the past ten years.

There have been only two branches of the industry which have not followed these principles but have relied on methods of the early part of the nineteenth century for their operation. These are the wrought-iron and the sheet-steel branches. The former, however, has seen the light within the last couple of years, and has passed from hand puddling to mechanical and chemical processes. There is every reason to believe that this change will produce substantial benefits for the wrought-iron industry. In the sheet industry likewise a more progressive spirit has appeared within the same period, and it remains only to see how helpful such steps as have been taken are likely to prove to the makers of sheet steel in the United States.

### Wide-Strip Rolling

The most expensive of the new developments has been the introduction of so-called continuous sheet rolling or, more correctly, the rolling of strip in sheet widths. The first attempt to do this proved to be a failure, partly because the economic conditions were not right and there was not enough business in given sizes to permit rolling continuously, and partly because the apparatus was not properly designed, and while it did turn out the product, there was so much trouble and such heavy maintenance costs as to make it impossible to compete with sheet made by more conventional methods. Within the last few years, however, a number of mills have been built which apparently are capable of rolling in an efficient manner, while the number of large orders for a few sizes has grown up to such a point as to make the economic operation of continuous mills feasible.

When the first continuous sheet mill was started at Butler, Pa., there was a very gloomy feeling, indeed, among the owners of non-continuous mills. While some of the claims as to the

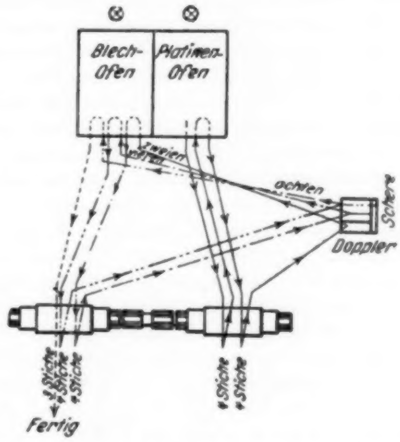

Fig. 6 German Double Mill for Five-Heat Process. Sheets 20.87 × 29.92 × 0.0126 In. From Sheet Bars 9.84 × 0.366 In., Rolled Singly

(Sequence of operations: 1, heating the sheet bars; 2, roughing, 4 passes; 3, reheating; 4, roughing, 4 passes; 5, doubling; 6, reheating in pairs; 7, rolling, 4 passes; 8, doubling and cutting; 9, reheating in fours; 10, rolling, 4 passes; 11, doubling and cutting; 12, reheating in eights; 13, finishing, 2–3 passes. One pack of 8 sheets single length.)

economic advantages of the continuous mills, such as that of saving $15 a ton on 22-gage sheets, were obviously wild, the sheet-mill owners were quite willing to admit among themselves that their plants might come to have only a scrap value within, say, two or three years. However, there is no such feeling today. On the contrary, the old-fashioned sheet-mill owner, or rather the owner of an old-fashioned sheet mill (these two are sometimes the same thing, but not often), is considering the situation quite cheerfully, and rather congratulating himself that he does not have a $5,000,000 or $7,000,000 mill on his hands and does not have to worry about paying fixed charges and facing possible revolutionary depreciations.

The fact is that at least in one respect the continuous sheet mill has failed, and that is in its ability to make sheets to sell at a profit. All that the continuous mill apparently can do economically is to produce breakdowns or material equivalent to that coming today from the roughing mill. Sheets have been rolled continuously to 18 gage. This requires, however, a considerable amount of coaxing and is not a general practice. Somewhat thicker sheets, such as 16-gage, can be produced with fair uniformity, but it is only at 14 and still better at 12 gage that the continuous mill shows up best. The wide-strip mill is therefore really doing only the work of the roughing mill, and the roughing mill in the non-continuous sheet mill of today is probably the most economical part of the equipment. The sheet bars are comparatively thick, hold their heat fairly well, and can be rolled easily and rapidly. They do not require as careful feeding as in pack rolling, and as a rule can be rolled down without reheating to the point where doubling or pack rolling comes in; and if they do need reheating they are cheaper and easier to handle than packs, because they are lighter and short, both of which make for cheaper handling. The continuous mill therefore really

leaves off at the point where the conventional finish rolling begins, and if the product of the continuous mill has to be finish-rolled in non-continuous mills, the saving is materially reduced, and when other factors are taken into consideration, it may vanish completely.

It should not be forgotten in this connection that the wide-strip mill of today is more or less a speculation. Its first cost is enormous and may vary from a couple of million to as high as ten million dollars. This means that the mill carries at 6 per cent an interest load which can vary from $120,000 a year to $600,000. But this is only the least of the fixed overhead charges, a much more important part being that of depreciation. Now, what should the depreciation on a wide-strip mill be? To answer this question it is only necessary to point out that the wide-strip mill is obviously a temporary expedient and can be considered as a permanent equipment only if and when a method of finishing is developed which will take the material from the wide-strip mill and convert it into salable sheets at a reasonable cost. Since no such method is as yet available and since it is the finishing of the sheet that constitutes the major part of the cost, it is entirely possible that a new method of operation will be developed which will render the wide-strip obsolete before it has had a chance to pay for itself. Such things have happened before.

The wide-strip mill has been a most interesting development and its mechanical success testifies to the very high status of mill engineering and to what can be done today when people make up their minds to do it and are willing to spend money. Certain problems which came up, however, are of considerable interest, one of the most important of them being how to control the movement of the sheet through consecutive pairs of rolls. The problem here differs materially from that encountered in conventional sheet rolling or conventional strip rolling. Mill engineers know that rolls have a tendency to lose their cylindrical shape and to be subject to what is known as "bellying," or an increase of diameter in the middle as compared with the ends. This can be remedied to a certain extent by making the rolls slightly concave, so that when the "bellying" takes place they will become truly cylindrical. Another method which has been suggested but not yet adopted to any conceivable extent is to machine the roll to a true cylindrical shape, operate it until it becomes hot, and while in that condition give it a further dressing which will bring it to cylindrical shape. Tools to do this are already available and it is merely a question of developing the necessary technique for doing the fine work required under rather unfavorable circumstances.

In conventional sheet rolling where the sheet bar or pack always travels through the same pair of rolls, a small amount of roll deformation not sufficient to affect the acceptance of the product is rather desirable, because it provides a guide for the sheet and makes it less likely for it to go crooked or shift sidewise. When, however, the sheet has to travel through a number of consecutive passes as in the strictly continuous mill or the cross-country mill, there is a possibility that the deformation of one pair of rolls may be out of line with that of another pair, with the result that the "guide effect" may be lost or may become a source of serious trouble. The American Rolling Mill Company at their Ashland plant sought to obviate this situation by deliberately controlling the deviation of the rolls from a true cylindrical shape and doing it in such a manner that the consecutive rolls would have gradually decreasing deviations from true cylindricity and be so arranged as to guide the sheet in a substantially straight line.

According to an editorial in *The Iron Age* of June 28, 1928, there are today two wide-strip-mill installations with a monthly capacity of 30,000 tons each, another one with 25,000 tons, one under construction with 30,000 tons, and two—one at Ashland and one in the St. Louis district—the capacity of which has not been officially given out but which may be estimated at 30,000 tons in one case and 20,000 tons a month in the other. This means an annual capacity of close to 2,000,000 tons a year, a tremendous amount to sell, particularly considering that the wide-strip mill is not economical except when it rolls fairly large quantities in one size.

### Rolling With Heating Between Passes

Another way to solve the problem of economic sheet production has been likewise initiated at the Ashland, Ky., plant of the American Rolling Mill Company. This installation deserves the most careful and sympathetic attention, because it embodies what appears to be a thoroughly sound principle. The only question is how economically the principle has been embodied in actual machinery. In this case the bar plates are sheared to lengths as they emerge from a holding furnace and are fed directly into a seven-stand jobbing mill which consists of four two-high 30-in. × 58-in. stands, and three three-high 30-in. and 14-in. × 58-in. stands. The product issuing from the jobbing mill varies in size according to the order being rolled, the length usually being about 10 ft., the width up to a maximum of 48 in., and the thickness ranging from $^1/_4$ in. down to 16 gage. The jobbing mill therefore corresponds to the roughing mill in the ordinary sheet mill. Following this the treatment given the roughed plates depends on the grade of sheets to be finished. Usually, the plates are matched in pairs, sheared on sides and ends, and

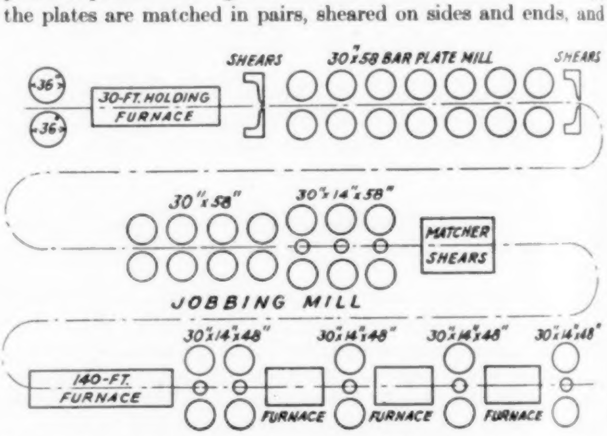

Fig. 7 Sheet Mill, American Rolling Mill Co., Ashland, Ky.

fed into a 140-ft. continuous heating furnace preceding the sheet mill. The mill consists of five stands of three-high 30-in. and 14-in. × 48-in. rolls, each stand being driven at about 25 r.p.m. Short reheating furnaces between stands 2 and 3, 3 and 4, and 4 and 5 maintain the material at the proper rolling temperature. Sheets of a maximum width of 41 in. and minimum thickness of 20 gage can be produced on this mill. Pairs of sheets are said to be finished at the rate of about 15 per minute. (T. J. Flaherty and A. F. Kenyon, in the *Electrical World*, July 21, 1928.)

The sheets after annealing and pickling are finished when necessary by cold rolling. The cold-rolling mill consists of eight trains of from 2 to 5 stands of 26-in. × 56-in. rolls. The usual practice is to give the sheets coming from the pickling machine about four cold-roll passes, then box anneal, and finally give a finish cold rolling of from one to four passes. The procedure varies, of course, according to the finish and temper required for the sheets.

The Ashland mill works on a correct principle in that the sheets in finish rolling are heated only sufficiently to carry them through stands 1 and 2. Reheating furnaces are provided between stands 2 and 3, 3 and 4, and 4 and 5, which means that heat must be added only to compensate for the loss in each pass; that is, the temperature of the metal can be maintained throughout

the rolling process within very close limits and the operation need not be controlled by the desire to save heat but can be carried out under the best physical and operating conditions without regard to the possible loss of heat that any delay may entail.

The only objection to this method is the very high initial cost thereof, which means that it is applicable only in mills which have a very large output. Considering, however, the enormous production of sheets in this country and the large market available, this is not a serious objection. On the contrary, should the Ashland method provide a satisfactory economy in operation, the high first cost might prove to be beneficial to the industry, in that it would concentrate production in comparatively few hands and make it possible to maintain in a legitimate manner prices that would give a reasonable profit to manufacturers of steel sheets. The other and more serious objection is that the process does not appear to be very flexible. This objection is stated with considerable hesitation, as the author is not fully familiar with the Ashland plant. It would appear, however, in view of the very large sizes of the furnaces, that variation of temperature would be quite difficult. Finally, there is a general objection to treating sheets, particularly those which have to be rolled to a fine finish, in any furnace heated by an open flame, which is based on two grounds. In the first place, no matter how carefully the temperature may be controlled, if any spot in the furnace is hotter than it is desired to have the sheet, the control is illusory. While it is true that a bright sheet does not absorb radiant heat well, there is no question that it can absorb in this way quite a large amount of heat. If the furnace roof or walls have a temperature higher than the sheet there is always a considerable amount of heat absorption which may easily be of local character, with the result that part of the sheet is heated to a greater extent than the rest. This remark is not made specifically with reference to the Ashland plant, but to all flame-fired furnaces.

The next objection to heating sheets between passes in open-flame furnaces has to do with the effect of this method on surface finish. Wherever there is an open flame there is spalling of the wall and roof of the furnace. The life of the bricks and lining in the furnace is limited. They are always breaking down, and this broken-down material has to go somewhere. As sheet is always present in the furnace, it is impossible to prevent a certain amount of furnace material from dropping on the sheet, and we all know what little things will spoil the surface of the sheet. Incidentally, furnace-wall material is not a trifling matter because of its abrasive nature and hence its ability to scratch the sheet and the rolls. Of course, the material being rolled can be protected to a certain extent by using what is known as a pilot sheet, i.e., an extra piece of metal to cover the sheet proper. This means, however, a not inconsiderable additional cost by way of material loss and extra handling, as well as a great increase in the duration and cost of heating.

## Surface-Combustion-Type Furnace

About a year ago a surface-combustion-type furnace was installed in the mill of a midwestern steel company for continuous normalizing of full-finish auto sheets. This furnace is about 102 ft. long with a 15-ft. preheat zone, a 45-ft. heating zone and a 34-ft. cooling zone. The fuel used is natural gas of about 1000 B.t.u. per cu. ft. heat content. The fuel consumption is said to be $1^1/_2$ cu. ft. per lb. The sheets annealed are 0.06 to 0.10 carbon steel from 16 to 22 gage and 48 in. wide in all lengths. The sheet enters the furnace at room temperature and leaves the heating zone at 1750 deg. fahr. It is held at 1500 deg. fahr. for a short time before final cooling to 1000 deg. fahr., the temperature at which the sheets leave the furnace. The temperature in each section is controlled without personal supervision or adjustment by three Leeds & Northrup automatic temperature-control instruments. The furnace is rated at $87^1/_2$ tons per 24 hr. with two men on the charging and two men on the discharging end. Special attention is called here to the output which is barely $3^1/_2$ tons per hr.

## Sheet Rolling in Germany

From time to time statements have appeared which have embodied certain wonderful claims in regard to performance in sheet rolling abroad, particularly in Germany. A careful study of the situation in the Reich would indicate that it does not differ much from that in America, and, if anything, things are not as far advanced there as here. W. Krämer, in an extensive series of articles published in *Stahl und Eisen* in 1927, begins by stating that "of the various rolling methods, that employed in the production of sheet steel is most unusual in that the skill and physical strength of the workman are still the controlling elements therein." That, of course, describes perfectly the American situation as well.

Methods of rolling are much less standardized in Germany than in America, and all kinds of combinations of roughing and finishing mills are employed. Among other things, the three-high mill is much more common in Germany than in this country. Table 2 gives substantially the German schedule of sheet rolling, while Tables 3 and 4 show the German outputs per mill and also incidentally give evidence that these outputs are lower than American outputs. At the same time it must be remembered that the German wages are less than one-third of the corresponding American wages. Fig. 2 shows diagrammatically the German layouts, which again do not materially differ from American layouts, except that the use of automatic doublers and matchers is somewhat less common in Germany than in America. The German industry incidentally works under the handicap that the production of the mills is very much lower than in America, which makes it less possible to put in improved machinery, should such be developed.

TABLE 2 GERMAN SCHEDULE OF SHEET ROLLING

| German gage | Thickness in mm. | Thickness in in. | Number of sheets in pack: Cold rolling | Number of sheets in pack: Hot rolling |
|---|---|---|---|---|
| 9–10 | 3.00–2.75 | 0.118–0.108 | Single | ... |
| 10–16 | 2.75–1.375 | 0.108–0.054 | 2 | Single |
| 17–20 | 1.25–0.875 | 0.0492–0.0344 | 4 | 2 |
| 21–22 | 0.75–0.625 | 0.0295–0.0246 | 12 | 4 |
| 22–25 | 0.625–0.438 | 0.0246–0.017 | 16 | 4–6 |
| 25–26 | 0.438–0.375 | 0.017–0.0147 | .. | 6–8 |

TABLE 3 OUTPUT OF GERMAN MILLS WHEN ROLLING HEAVY GAGES

(In metric tons per turn of 10 hours—see note below)

| Thickness in mm. | Thickness in in. | Three-high | Two-high, cold |
|---|---|---|---|
| 1.5 | 0.059 | 20–24 | 8–10 |
| 2.0 | 0.078 | 23–27 | 12–15 |
| 2.5 | 0.098 | 25–30 | 15–17 |
| 3.0 | 0.118 | 35–40 | 16–20 |

NOTE.—These figures apply to a layout comprising one roughing stand to one finishing stand, and efficient opration. The cold-rolling stand rolls run at 50 to 60 r.p.m., corresponding to a velocity of 1.8 to 2.1 meters (5.70 ft.) per sec.

TABLE 4 OUTPUT OF GERMAN MILLS OF LIGHT GAGES

(Finishing stand, in metric tons of turn of eight hours)

| Thickness, mm. | Thickness, in. | Output, tons |
|---|---|---|
| 0.5 | 0.0196 | 6.5–7 |
| 0.4 | 0.0157 | 6.0–6.5 |
| 0.32 | 0.0126 | 5.5–6 |
| 0.28 | 0.0110 | 4.5–5 |
| 0.22 | 0.0086 | 3.5–4 |
| 0.20 | 0.0078 | 3.3–3.8 |

## The Sheet Mill of the Future

It will be of interest now to look into the future, and in a general way to see what an ideal sheet mill may be expected to resemble.

Starting with the sheet bar, the 8-in. size is practically standard

today. It has, however, been adopted not because of its convenience in rolling but because its weight is such as to make it easy for the roller and catcher to handle, and particularly for the latter, as he has to elevate the bar by tongs to the level of the upper roll. There have already been objections made to this width of bar because it is not really economical, and furthermore, a longer bar would probably give a flatter sheet. Nevertheless, even the change to a 12-in. bar has been successfully resisted because of the greater difficulty of handling the heavier piece. Should mechanical means of handling be introduced, this objection would disappear, and in such an event there would be no reason why a 24-in. bar should not be used. This would cut in three the work at the bar shears, reduce, to some extent,

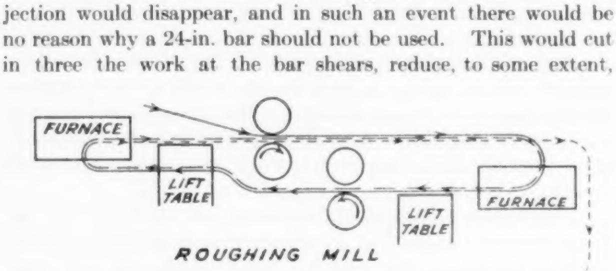

Fig. 8 Sheet Mill of the Future

waste on trimming sheet ends, and very materially increase the production of the roughing mill.

The next question is the temperature of the pair furnace. As a rule it is much too hot today. There is no reason why plain carbon steel should be heated above 1500 deg. fahr., a temperature which presumably is under the scaling point. This would permit pickling the bars before charging them into the pair furnace, which again would mean reduced cost of pickling, materially increased (in terms of tonnage of sheets) production of the pickling machine, and greatly decreased cost of the latter, because of the fact of handling shorter pieces than today. As reheating furnaces of a proper type will be provided in the future between passes, substantially as they are today at the Ashland plant of the American Rolling Mill Co., it will not be necessary to heat even the sheet bars to a temperature higher than required for the first two or three passes, and very likely the temperature ultimately selected will be much below the 1500 deg. fahr. mentioned above.

### The Roughing Mill of Tomorrow

Just what the roughing mill of the future will be it is difficult to say today; most likely several types will be employed. For a very large output the cross-country or tandem type of mill would naturally seem to be indicated, except for the fact that a constant distance would have to be maintained between the stands of the cross-country mill, while the length of the sheet varies. The result would be that in rolling shorter sheets there would be a certain loss of time and probably complications in the control of the heating furnaces to compensate for the increased lineal time that the sheet remains in the interstand furnace. This may, however, be accomplished by controlling the speed of travel of the sheet through the furnace, although these additional complications would not be welcome to the mill operator.

Where the cross-country mill is not acceptable either for the reason stated above or because of lack of space, or finally because the volume of production does not justify the comparatively large initial cost of such a mill, several other types are available. The three-high mill would probably be the first to be considered, as it is well known. With comparatively simple manipulating devices it can attain a very large production, and it is simple and cheap to operate. On the other hand, such a mill has one very grave disadvantage when it comes to rolling sheets, a disadvantage, however, which, as shown by German practice, is not too serious in the case of rough rolling.

This objection, or rather, difficulty, lies in the fact that, as stated previously, in sheet rolling both rolls are seldom truly cylindrical in shape. Roll treatment has developed to a point where it is more or less possible to maintain a pair of rolls in sufficient consonance of shape to permit good rolling, but in a three-high mill it becomes necessary to keep three rolls in a proper sequence of shapes.

The next mill that would come under consideration would be a "three-high" in which the middle roll is divided in two. A mill of that kind would consist of two two-high mills so arranged that the sheet going through mill No. 1 would make its exit above the top roll of mill No. 2, while the sheet going through mill No. 2 would pass below the bottom roll of mill No. 1. The two pairs would be always running in the same direction, but the direction of pair No. 1 would be opposite to that of pair No. 2. Proper tilting or lifting tables may be provided on both sides.

Finally, the present single two-high mill might be retained, but equipped with manipulators which would receive the sheet at one end, pass it over the top to the other end, and feed it into the mill again. The manipulator here would really do the work of the catcher. Of course, it would be quite easy to equip even the mill of today with such a manipulator, and there might be some advantage in doing it, but this advantage would not be very great because the rough-rolling part of the work is not the most expensive one. On the finish-rolling end such a device would not be advisable at all today, because with present methods of pack rolling and repeated reheating of the pack the saving through the use of a manipulator would not be large enough to justify the additional expenditure. On the other hand, if these manipulating devices were combined with reheating furnaces, then the pack would go through the mill and into the reheat furnace; from there the manipulator would take it back into the mill so that a pack could be completely finish-rolled without the need of dragging it to an outside furnace. With such an arrangement extremely rapid handling of the pack would become possible without imposing unreasonable strain on the men. Furthermore a very close control of temperature of the sheet could be maintained, assuming, of course, that the furnaces were of a suitable type. The speed of the rolls could be materially increased as the manipulators would be capable of taking the sheet from the mill at practically any speed at which the mill could deliver it. Calculation has shown that with such an arrangement the mill crew could be cut down to less than one-quarter of what it is today, the production of the mills could be doubled and perhaps tripled, costs could be materially reduced, and quality, especially surface quality, greatly improved.

### Great Changes in the Sheet Industry Inevitable

There is no doubt of one thing, and that is that the industry cannot continue in the way it is going on today. No industry in America can be efficiently carried on if it has to rely on labor which is at once highly skilled, willing, and capable of doing intense physical work. *The sheet industry cannot long continue to produce goods at the present costs and sell them at the present prices,* or at least at the costs and prices prevailing in the case of the majority of the producers. Changes in the industry are inevitable, especially in the direction of modified methods of production, which will unquestionably be based on the replacement of manual-

labor operation by manipulation by machinery, substantially as has already been done in all the other branches of the steel industry. The economic side of the industry will also have to be reorganized in the direction of reduction of the number of plants and concentration of output in larger and better-equipped units capable of meeting the strenuous specifications of today in an economical manner and knowing enough about their costs to demand a fair price for their products.

As a matter of fact, nothing radically new is here suggested. It is merely stated that the sheet industry cannot continue to be an exception in methods of production, as it is today, but will have to adopt the same principles of mechanization as have already been adopted by the remainder of the steel industry, and as are being adopted by other backward industries, such as bituminous-coal mining and agriculture. The Queen told Alice, of Wonderland fame, that in the Land Reached Through the Looking Glass "you have to be running as fast as you can in order to stay where you are." This is a true picture of modern industry. The sheet-steel industry has played the part of the Sleeping Princess for most of the time in its two hundred years of history—but industrial sleeping princesses are wakened from their slumbers, as a rule, by a splash of red ink.

Mechanically, changes will take place in the direction already clearly indicated by such mills as the Ashland plant of the American Rolling Mill Company, while the employment of a longer sheet-bar will make the operation of the wide-strip mill as a producer of sheet-mill breakdowns useful and possibly even profitable.

### Sheet Prices by Condescension

It might be well perhaps to touch on two matters in this connection. One is the talk going the rounds of the steel industry generally, and the sheet industry in particular, as to the necessity of educating the purchasers of steel products to pay higher prices for these products, thus eliminating what the sellers are pleased to call "ruthless" buying. This is the old story of the mice who met and decided that all cats should submit to having their teeth drawn. So far as history shows, this project has never succeeded. If buyers can buy cheaply, no association of sellers can induce them to pay more than the prevailing market price, and furthermore the buyers may, if they care to, remind the sellers of the time not many years ago when the boosting of prices by manufacturers was far more "ruthless" than is the depressing of prices by buyers today. It would be dangerous for engineers to rely on any such attempt to persuade purchasers to be superkind to sellers without a corresponding obligation by the latter to be good to purchasers should the tables be reversed, and of course no group of manufacturers can agree to any future maintenance of prices with the Federal laws governing this subject as they are today.

### Patents in the New Sheet Industry

Continuous sheet rolling, which is not a new art at all, but which has been developed to the commercial stage within only the last two years, is literally plastered with patents, particularly as regards details, accessories, handling apparatus, and the like. Unless the sheet-steel industry is alert, it will be worse off in the matter of patents than the radio industry is today, than which it would be difficult to find a more horrible example. The automobile industry has found a way out by what is known as the cross-licensing agreement, which, in its case, was possible because the most important technical developments were made within the industry, and because by the time the cross-licensing agreement was entered into by the automobile industry the main features of the automobile design had become common property, while the only serious patent threat, the Selden patent, has been smashed in the Ford litigation. Judging from the past, any development in the sheet industry will have to come from outside, so that a cross-licensing agreement patterned after that employed by the automobile industry would not be helpful here. Whether or not the Flat Steel Manufacturers' Association could be used as an instrument for acquiring patents affecting the entire industry and licensing all members, is a question which the industry itself will have to solve. To engineers, however, it would seem to be a highly wasteful and possibly dangerous situation by which they may be prevented from using important devices or be made to pay exorbitant licenses for the use thereof.

In the first paragraph of this paper the author ventured to state that while the industry is approaching the date of its second centennial, it is mentally only twelve years old. An industry which after two hundred years of existence is facing a complete reorganization and which in two hundred years has not evolved from the stage where it operates by brawn and sweat can be considered as being no more than twelve years of age mentally, particularly when compared with all other branches of the steel industry.

## Discussion

John W. Sheperdson.[2] Every product that is manufactured is governed in its price policy by supply and demand. Supply and demand together constitute competition. I do not agree with the author of the paper that the sheet-rolling industry is engaged in ruinous competition, or that it has a mentality equivalent to a boy 12 years old. On the contrary, I am convinced that the hot rolling of thin gages in wide widths has been and continues to be a problem to tax the wisest and most experienced rolling-mill men.

The problem of hot sheet rolling by the continuous method is much the same as the hot rolling of other small products by this method. Rods in large-weight bundles or narrow strips of thin gages and long lengths call for high delivery speeds to be able to produce them at all. High delivery speed spells high output, and high output spells ways and means of getting rid of the product to make room for the oncoming product. How can continuous rolling of any kind be justified unless it be done at a high rate of production? We all know what part the investment per ton of annual production plays in final costs; we simply must have a large divisor with a large investment.

Fundamentally, any method of manufacturing a product has its limitations. For instance, the Garrett type of rod mill is limited to a small rod bundle weighing around 180 lb. Any rod mill is ill adapted, except under unusual circumstances, to roll smaller than No. 5 rod. Beyond that point it is generally cheaper to cold-draw.

In the days of three-high sheet-bar mills, sheet bar was regarded the lightest section suitable for rolling on such mills, and could only be produced in short lengths from a small bloom or small ingot.

The continuous sheet-bar mill installed at the plant of the Youngstown Sheet and Tube Company some 23 years ago rolled this product for the first time from a whole 6500-lb. bloom direct from the ingot heat, and fitted into the scheme of the then prevailing, and for that matter now prevailing, system of sheet rolling.

The transition now in course of evolution in the production of sheets is to carry a semi-finished intermediate product down to lighter gages, at higher speeds, but up to the present no attempt has been made to do this from the initial heat of the ingot nor in weight of slab corresponding to the whole ingot. Therefore, reheating is a part of this new process.

[2] Chief Engineer, Morgan Construction Co., Worcester, Mass. Mem. A.S.M.E.

The difficulties are well recognized: speed, high tonnage per minute, and heavy torques mean power, and power beyond all previous concentration is being put into small rolls.

New metal in the rolls of sufficient endurance to withstand the localized pressures is required. These new rolls cannot come overnight. The American sheet-mill industry, far from showing temerity, has plunged into a new process pretty much regardless of cost, allured by potential advantages in sight. This is no twelve-year-old boy's job.

The problem before the sheet mills lies in finding if the old dividing line of economical production at sheet bar can be pushed forward and nearer to the finished sheet, or, stated another way, the problem is whether or not the cost of making some new semi-finished product, consisting of prime cost plus investment and carrying charges, can show a saving over the long-established practice of producing sheet bar at very low cost in a continuous mill, direct from the ingot heat, and then breaking down this sheet bar in hand roughing mills. Any figures I have been able to make do not point to net savings over the old method.

I do not think that the author has shown us conclusively how to build the next sheet plant, but he has brought to our attention the evils that now exist.

D. Eppelsheimer.[3] The author has sketched in a very interesting manner some of the features and possibilities of the recent development in continuous rolling of flat wide metal. The writer feels, however, that in discussing the economic importance of the new process of rolling, mention should be made of the developments in the finishing department which must be followed if full advantage is to be gained from the new continuous-rolling treatment.

It must be evident that new and advanced modes of pickling, annealing, cold rolling, and coating are of necessity employed in order to gain full benefit from the higher production of the continuous rolling.

The author has well stated one of the objects of the new process of the American Rolling Mill Company in its plant at Ashland. The writer might add, to avoid a misconception of his meaning, that the control of the shape of the rolls in successive stands of a tandem or continuous mill involves much more than the original turning of the rolls and heating of them by the piece. The shape between the rolls when the piece is being engaged is the critical thing, and it must be appreciated that this is affected by a number of factors ranging all the way from the rigidity of the mill housings to the character of the lubrication of the roll necks or bearings.

There are a number of problems other than those mentioned in the paper which required solution in order to substitute mechanical operation for the high degree of skill required by the hand rollers of the past. A discussion of these points is probably out of place before this group, which are not directly interested in the technique of sheet rolling, but it is believed that a full understanding of them would convince the members of the Society that the author has underestimated the difficulty of replacing the particular manual operations involved by a series of mechanical devices.

As stated in the paper, in the Ashland process the shape of the rolls when in engagement with the piece is deformed from the truly cylindrical, and the shape in each stand is less deformed than in the preceding one. This process of rolling wide, thin metal is used not only at Ashland, but at Butler and Middletown and by licensees of the American Rolling Mill Company at Weirton, and will be used shortly at Wheeling, and undoubtedly has a much wider application than the author apprehends.

Those members of the Society who visited Ashland will recall that the continuous pack-rolling units of the mill installation are planned so as to operate in parallel with each other, as well as in series with the continuous roughing mill, and it may be added that our experience indicates that it is fully practicable to provide continuous or tandem finishing mills, operating always according to the deformation process noted by the writer, for reducing sheet metal to any desired gage with large attendant economies.

With regard to the patent situation, it may suffice to say that the process referred to by the author of the paper as the Ashland process and discussed above has been recognized as patentable not only in this country but in many foreign countries.

The writer has had personal connection with the development of the patent situation of the American Rolling Mills Company, and has attempted to keep informed on the patent situation in general. To his mind there is no basis for a fear that rival concerns are on the way to, or are even unconsciously drifting into, the position of interfering with each other by means of trivial patents. The entire situation was, as he believes, so completely worked out by the American Rolling Mill Company before the industry became convinced of the practical importance thereof, that there is but little room so far as this development is concerned for the automobile or radio situation to be repeated.

R. J. Wean.[4] The author is to be commended on the frankness with which he has confronted the sheet industry with what he considers their shortcomings. In this brief discussion it may therefore be well to give due credit to the accomplishments of those engaged in this great industry, whose total output this year will approach five million tons, having an approximate sales value of from \$300,000,000 to \$400,000,000.

When it is realized that the sheet and tin plate industry has invested upward of \$75,000,000 in the last two years for the production of tinplate and sheets by new methods and processes, they cannot, in all fairness, be accused of a total lack of progressiveness.

While it is true that for many years the industry was slow to take up new developments, it must be remembered that this was during a period when profits were ample to satisfy the stockholders and the pressure of low selling prices was not present. In recent years the industry has made tremendous strides in the improvement of the quality of its product, and has also greatly increased production from existing equipment.

For many years the sheet industry was largely in the hands of mill men—men who had been trained to roll steel by actual experience. Very little engineering knowledge was applied to the industry as a whole, and this possibly accounts in some measure for the lack of progress, as in recent years the developments that have taken place in the sheet industry have been brought about by applying engineering effort. This has been done, in most cases, by the companies producing sheets, rather than by those outside of the industry.

As was stated by the author, probably the greatest development in the industry has been that of rolling wide-strip steel. The product from these mills is already being used in a wide market.

Strange as it may seem, the introduction and development of wide-strip rolling when used for tin-mill breakdown purposes caused the development of new methods of heating, as well as new methods of finishing this material, that can be applied to

[3] American Rolling Mill Co., Middletown, Ohio.

[4] Vice-President, Aetna-Standard Engineering Co., Youngstown, Ohio.

any existing conventional-type sheet or tin mill. Continuous pack-heating furnaces and mechanical catchers for the mills constitute largely these improvements at the present time, and this permits an increased output per mill with a reduced mill crew.

These developments are available to all producers under license, and some producers have already taken advantage of this in both the sheet and tin-plate industries.

In past years on full-finished or automobile sheets it was general practice for the bars to be roughed down from two to four passes on the roughing mill and then swung to the finishing mill where they would be given several additional roughing passes before matching. The pack would then be returned to a sheet furnace for reheating, and subsequently finished on the finishing mill.

When operating in this manner, one crew would operate both the roughing and finishing stands. The result would be that either one of the mills would be idle 30 to 40 per cent of the time, and in many cases even more. During the past year what is known as the "double-mill" or "Tipperary" system has come into quite prominent use, the roughing mills being operated by one crew and the finishing mills by another, so that all mills are operated as nearly 100 per cent of the time as heating and mill conditions will permit.

Many sheet producers thought that this would not be practicable, but it has been proved within the last year that it is not only practicable but highly desirable; and this system will lend itself very favorably to the installation of continuous heating furnaces and mechanical appliances not only to cut down the labor required but also to step up production. To the writer's knowledge as much as 25 to 30 tons of 19-gage sheets 36 in. wide, and 78 in. long, rolled three in a pack, were finished on a sheet mill of the above type in eight hours. When this is compared with the old-style production of 9 to 12 tons in eight hours, it can readily be appreciated what this will mean to the sheet producer in the form of reduced cost, as well as increased tonnage, without the addition of any actual rolling equipment.

When all of the economies of this nature have been accomplished in what we shall term the "conventional-type" sheet mill, it will be extremely difficult for wide-strip-steel producers to manufacture at a lower cost than the ordinary sheet-mill producers.

It was stated in the paper that the cost of a sheet mill was \$25,000.[5] Lest there be some misunderstanding, it may be well to clarify this to some extent. This represents—and the writer thinks it is low—the cost of a hot-mill stand, but does not include any other plant equipment. The actual cost today for erecting an 8-stand sheet mill would run from \$1,500,000 to \$2,000,000, or about \$250,000 per hot mill. This of course would include buildings, furnaces, and other machinery, without which it would be impossible to operate the mill.

The foregoing facts and the completion of present developments will probably demonstrate that the sheet industry is very much alive to its problem and well on the way to at least a partial solution.

Lloyd Jones.[6] When the writer recalls to mind the various specifications as to gage, surface conditions, and physical properties required of the modern sheet maker, he is inclined to believe that that individual is entitled to a mentality rating far in excess of the one given in the paper.

In regard to the distinction between sheets and strips, there need be no confusion in the steel industry. Sheet-mill and strip-mill practices are radically different, as any one familiar with the art knows. The fact that sheet manufacturers will slit sheets into strips and the fact that the strip manufacturers will cut strips into sheets has nothing to do with the fundamental differences between the two processes of manufacture.

Sheet practice over a long term of years gradually developed into widths up to 64 in. The strip process over a period of years has steadily been increasing in widths, and the fact that the range has recently been increased up to 42 in. is a logical development and not a new and startling innovation as many would have us believe.

The author has ably covered sheet-rolling practice, but the writer cannot agree that the wide-strip mills have proved a failure. Of the last three wide-strip mills to be put in operation, two exceed expectations in thinness of gage and the third is producing within the limits of gage for which it was designed.

It is true that under the present hot-strip practice 12 to 16 gage may be considered commercial limits in wide widths, but with the addition of cold rolling these strips can be reduced to any gage desired. The writer cannot see anything fundamentally wrong with the strip process and believes that it is merely a question of time until these latest mills will be operating satisfactorily.

In his further treatment of the wide-strip mill, the author overemphasizes the difficulty of controlling the movement of a single continuous strip through successive stands of rolls. The strip-rolling process, both hot and cold, has been practiced for quite a few decades and the writer has not yet been converted to the idea that the control of the strip going through the mill has been only recently accomplished, by means that are new and novel.

The writer does not believe that the Ashland plant of the American Rolling Mill Company will be duplicated, and is of the opinion that future developments will instead follow along the lines of the old-established hot- and cold-rolled strip process.

The writer's vision of the sheet mill of the future is radically different from that set forth in the paper. The mill, as he views it, disregarding the raw-material manufacturing end, such as blast furnaces, open hearths, slabbing mills, etc., and starting from slabs of required widths and in thickness ranging from 2 to 3 in., would first consist of a modern wide hot-strip mill divided into two sections, a tandem roughing section and a continuous finishing section. The product of this mill might range from 12 to 36 or 42 in. in width, as desired. In thickness, covering the entire width range, the mill should be capable of rolling in lengths, say, about 250 ft. long, gages ranging from 3 (max.) to 26 (min.). By this he means hot-rolled strip 36 or 42 in. wide, and 26 gage thick. With such a range of widths and gages, the mill would cover jobbing-mill plates and sheets within the width capacity in all gages, sheet-mill products within the width capacity, and ball gages down to 26 gage—probably 75 per cent of the sheet tonnage.

As to tin-mill products, the mill would cover 18- to 22-gage material, which could be doubled and hot rolled on a hand mill to light gages. An alternative to this would be cold rolling on cluster or backed-up mills to the desired gage.

Besides covering 75 per cent of the common sheet tonnage, the mill would produce suitable gages covering the entire cold-rolled strip industry and the full-finished sheet industry within the width capacity of the mill, namely, 36 or 42 in. wide.

It should be noted that with the proper equipment of the blue annealing furnaces, cold-rolling mill, tin and galvanizing pots, etc., the installation will no longer be a single-purpose one, but a layout covering a wide range of products, flexible in character and one which, the writer believes, will be more economical in operation than our present-day plants.

It sometimes requires a great deal of courage for an engineer to predict the future, but the writer bases this picture on his knowledge of the present hot- and cold-rolling industry and also

[5] This of course should have been \$250,000, as in the original manuscript. The mimeographed paper distributed at the meeting contained the misprint of "\$25,000."—Author.

[6] E. W. Bliss & Co., Salem, Ohio.

on the fact that hot strips of long length 24-gage thick have been produced from a hot slab in one rolling without reheating by a new process recently developed.

In closing the author cautions the sheet industry not to become involved in a patent situation similar to that existing in the radio industry. Personally, the writer does not believe the sheet industry needs fear such a condition, because the sheet industry is 200 years old and the strip industry probably 60 years old, while the radio industry is the product of the last few years. If attorneys and inventors will familiarize themselves with the art, not only as it exists in the patent office but as it has been and is practiced, no confusion need arise.

H. L. Bodwell.[7] While the author's statements as to the apparently slow progress made in the rolling of sheet steel mechanically or semi-automatically, as compared to that made in other lines of steel products, are no doubt true to a considerable extent, the writer cannot refrain from taking some exception to the indictment that the mentality of the business is but twelve years of age.

Producers of sheet steel have, for a great many years, been alive to the desirability of some form of continuous rolling with the consequent elimination of at least a part of the expensive and laborious hand labor incident to the present practice, and great amounts of thought, effort, and money have been expended on the problem in the way of experimentation.

The difficulties heretofore have been largely of an engineering nature, due to the lack of mechanical devices not yet invented, or the lack of knowledge or experience in the behavior of the material being handled under the different conditions to which it is subjected in the process. It is peculiarly fitting, then, that such a paper should be read before a body of mechanical engineers, such as this. The field for the application of inventive genius is unlimited. The continuous or semi-continuous process of rolling from ingot or slab, on the initial heat or with some intermediate continuous heating, to the finished sheet or "broad strip" has already reached a highly satisfactory degree of development in so far as heavy gages are concerned.

The general plans and details of operation and construction of these continuous mills have been fully covered in various papers read before societies or published in the trade journals. No further description is necessary at this time. As mentioned in the paper, there are continuous mills in existence today capable of rolling 50 to 60 gross tons per hour into strips of 14 gage or heavier, up to 48 in. wide and into 16-gage or 18-gage up to 32 in. wide, at a saving in labor as compared to the similar roughing operation on old-style mills of $5 to $6 per ton.

The further reduction of the hot-rolled product to lighter gages, such as 22 or even 24 gage, is also accomplished successfully by means of continuous 4-high cold-roll mills. The product from such a mill is available for sale as ordinary black or blue annealed in jobbing-mill gages, up to 48 in. wide, and by further reductions and combinations of treatments, such as pickling, cold rolling, annealing, or normalizing, for sale in 20 or 22 gages, of limited widths and whatever grade as to finish or drawing qualities may be desired.

Such a mill can also act as a feeder for the old style of finishing mill, either in so-called bar plate cut to the proper width to furnish the weight necessary for the gage and size of sheet to be rolled in such thickness as to do away with the present old-style roughing mill, or by furnishing sheets already roughed to receive whatever further treatment is necessary on the old-style finishing mill to obtain any grade or gage desired, thus doing away entirely with the roughing operation and thereby increasing the capacity of the finishing mill.

The successful operation of a continuous mill of the type in question is manifestly a large-tonnage proposition and can only be carried on economically when the quantity and character of orders are sufficient to keep it in continuous operation. The limitations in gage and widths existent with the present forms of continuous mills will no doubt be gradually raised as experience is gained and mechanical and electrical devices are perfected for more accurate control of screw pressure, roll temperature, and speeds.

The problem of hot-rolling sheet widths continuously from slab or bar, with or without intermediate heating, into light gages, such as 24 gage and lighter, is vastly more difficult of solution.

A brief description of the present method of rolling light-gage sheets will possibly assist in the visualization of some of the difficulties involved.

While the fundamentals in the method of rolling light-gage sheet iron remain about as they were when the industry was first introduced into this country from Wales early in the Nineteenth Century, there have actually been many developments made tending to improve the quality and quantity produced per unit and to reduce the laboriousness of the work as well as better the working conditions.

The rolls have increased from 18 or 20 in. in diameter to 30 or 32 in., with corresponding increases in the size and strength of the housings and drives. Methods of heat control of the rolls have been perfected so that variations in temperatures are held within 50 deg. fahr. in all stages of the rolling operation, with consequent longer life of rolls. Roll breakage is now a rare occurrence, and it is usual to obtain a life of roll of 100 days or more before it has to be discarded on account of the removal of the entire chill.

Preheating of rolls is practiced, eliminating the necessity for making a large amount of more or less unsalable warming-up sizes, and permitting the immediate rolling of orders, with consequent better deliveries.

Continuous pair furnaces are used, with less labor in charging and elimination of puddling, and with improved quality of pair heating. Mechanical doublers have been introduced, doing away with one of the most difficult jobs. Various mechanical means of handling bars and packs into sheet furnaces and at mills have been devised. Working conditions have been improved by the installation of water-cooled floors, ventilating systems, and forced-air cooling systems. On the whole, many improvements have been made and the output per mill has been doubled during the last twenty-five years.

The rolling of sheets has remained to this day a process requiring a great deal of skill and close supervision on the part of the rollers, combined with considerable laborious work performed in comparatively difficult surroundings.

The standard mill unit consists of a roughing mill, sometimes called the "soft" mill, with both top and bottom rolls driven; a finishing mill with only the bottom roll driven, the top roll being driven by friction; and the necessary complement of pair and sheet furnaces, shears, doublers, etc.

The roughing rolls may be of steel or gray iron, but usually worn-out finishing rolls are utilized. They are kept cold by means of a spray of water. The finishing rolls are of cast iron, with about $^3/_4$ in. of chill, 28, 30, or 32 in. in diameter, of a length suitable for the ranges in widths to be rolled, varying from 34 in. in length of barrel to 84 in., and weighing from 8000 to 25,000 lb. They are run hot, but kept below about 750 deg. fahr. by means of steam or air blower. The crew consists of the roller, who is the foreman of the crew and has general charge of

[7] Assistant District Manager, American Sheet & Tin Plate Co., Vandergrift, Pa.

all operations on his mill, and a sheet heater, roller's helper, heater's helper, rougher catcher, pair heater, pair-heater's helper, matcher, doubler, shearman, leader, and opener. Additional help is provided as required because of excessive weight of bars or for other reasons.

The bars are drawn from the pair furnace in pairs and broken down on the soft mill until approximately $^1/_4$ in. thick, then are swung over to the finishing mill where the roughing is finished, the rougher and catcher doing this work. The two pieces are matched together at a convenient length and thickness, and the roughing finished in that way.

After the roughing, the breakdowns are matched or doubled, and reheated in the sheet furnace. After reheating, if 28 or 30 gage, 72 to 84 in. long, the pack is run over on the finishing mill one pass, then opened, matched, and doubled again. The pack now consists of eight sheets and is reheated again in the sheet furnace and finished by the roller in as many passes as necessary to obtain the required length. Twenty-six gage is matched in threes after roughing and doubled into packs of six, then reheated and finished. Other gages are rolled either single or doubled in twos, threes, fours, as may best suit the particular gage and size being rolled. The bars are generally worked in heats of twelve pairs each. Both bars and packs are, at some stage of the process, worked below the critical temperature.

The different parts of the process are carried on by different members of the crew, each man having his designated duties to perform. As the greater part of the roughing, the run-over, and the finishing are done on the one finishing mill, those members of the crew performing each part have ample time to rest.

The hot-finishing rolls are kept almost constantly in use, and are therefore kept at a uniform temperature.

The duties of the various members of the crew are pretty well implied by the names given to them.

The pair heating must be carefully done in as nearly a reducing atmosphere as possible, and overheating and scaling avoided so as to save trouble later from open surface and pair-furnace scale or dirt. The rougher must rough straight and uniform to length so that the matching can be done properly. The matcher and doubler must match square on sides and ends, and double so the ends will be even in order to save head scrap and secure uniformity of gage and weight of sheet. The sheet heater must see that the packs are heated thoroughly and evenly in a reducing atmosphere and not overheated so as to avoid finishing scale, open surface, and non-uniformity to gage.

The roller, when finishing off the heat, must see to it that the condition and shape of his mill are correct for the material he is finishing. To this end he must see that the roll temperature is right and also the temperature of the necks, as variations in either will produce poor work. The surface of the rolls must be kept smooth by frequent polishing to avoid pitting or marking of the pack surface. The pack must be opened up, if necessary, before it is entered, in order to avoid patching and jumping.

Proper screw pressure must be given to avoid twisting, squeezing, flopping, or sticking, and the roller must watch the draw to avoid excessive length which will result in scrap loss and lightness of gage.

It will be seen that close, skilful supervision is required over all stages of the process in order to avoid the damaging effect of any irregularities, and that light-gage sheets are peculiarly susceptible to damage from a great many causes.

In the case of continuous rolling it would be all the more necessary to guard against any damaging effects, as corrections would be more difficult and a large amount of material might be ruined in a short time.

Whether the development of the continuous process of rolling the lighter gages in commercial sheet widths follows the present idea of the broad-strip mill or the continuous reduction of packs through successive passes, it is obvious that even more refined methods of adjustment and control will have to be devised than are sufficient in the mill for rolling heavier material. Not only will pressure of screws, temperatures of rolls and roll necks, or consequent shape of rolls need to be under absolute automatic control, but it will be necessary to maintain a uniform degree of heat in the material being rolled by some form of non-oxidizing application of heat between the successive passes. It will also be necessary to be able to change quickly from one gage and size to another.

These difficulties all seem of great importance and very difficult to overcome to those who are familiar with the sheet-rolling industry, but there is no doubt that they will all be surmounted if a sufficiently insistent demand arises.

Lane Johnson.[8] The author's statement that "at least in one respect the continuous sheet mill has failed, and that is in its ability to make sheets to sell at a profit," deserves careful consideration.

At this time, there are operating in the United States six wide-strip mills: The Ashland, Butler, Trumbull, Weirton, Gary, and Middletown. Ashland, Butler, and Middletown are owned by the same company and the other three by individual companies. At least three of these mills are producing full-finished sheets of 22 gage by strictly continuous hot and cold rolling. The fact that five of these six mills are operating now and have operated for a long time on schedules which approach the capacities of the mills indicates that the author's statement about profits is subject to a reasonable doubt. The sixth mill in the list has been in operation about two months and is being brought steadily into high production. The four companies which own these mills are large, well managed, and are accustomed to making profits.

The author, however, brings out one important point. It is the fashion in America to do things mechanically rather than by hand. Beyond question the continuous wide-strip mill does reduce the amount of hand labor required to roll flat steel, whether it be plates, strips, sheets, or tinplate.

### Author's Closure

My innocent remark to the effect that the mental age of steel sheet rolling is only about twelve years seems to have displeased practically every one of the discussers, and yet, nearly every one quotes facts which support my contention. John W. Sheperdson says that the American sheet-mill industry has plunged into a new process pretty much regardless of cost allured by potential advantages in sight. Plunging into something to the tune of about seventy-five million dollars "regardless of cost" under an allure shows the mentality of a green boy and not the mature mind of a full-grown man. Such temerity might be excusable if successful, but Mr. Sheperdson himself points out that any figures that he has been able to make do not point to net savings over the old method.

R. J. Wean acknowledges that very little engineering knowledge was applied to the industry as a whole, and sees in this the reason for its lack of progress. H. L. Bodwell goes still further and quotes lack of knowledge or experience in the behavior of the material being handled in sheet mills. What can one say about the mentality of an industry which has been in existence for two hundred years and does not know yet enough about the properties of the materials from which it makes a living?

The next statement in my paper to which objection is made

[8] Chief Engineer, United Engineering & Foundry Co., Pittsburgh, Pa.

is that the wide-strip rolling failed in at least one respect, and that is, ability to make profits. In this connection, attention may be called to the statement by Mr. Sheperdson already quoted above, namely, that his figures do not show any saving in the new process as compared with the old. Mr. Wean also states that when the conventional-type sheet mill has been properly developed "it will be extremely difficult for wide-strip-mill producers to manufacture at a lower cost than the ordinary sheet-mill producers." If, now, the wide-strip mill does not make better goods and cannot make cheaper goods, why did the sheet industry spend seventy-five million dollars to install them?

This is particularly pertinent as Mr. Jones agrees with me that under the present hot-strip practice 12 to 16 gage may be considered commercial limits in wide sheets. We all know, of course, that within those limits the conventional sheet mill is also very efficient.

Mr. Eppelsheimer disagrees with my warning to the industry in reference to possible patent troubles. He says that the American Rolling Mills Company is collecting royalties from several other steel companies and is perfectly well satisfied with the situation. He does not say, however, whether these arrangements are in the interest of the company or of the industry.

# The Manufacture of Nickel-Steel Plate

By CHARLES McKNIGHT,[1] NEW YORK, N. Y., and W. G. HUMPTON,[2] COATESVILLE, PA.

*This paper deals with the manufacture, rolling, and inspection of steels containing between 2 and 3 per cent of nickel and which are used in boiler construction, and particularly with the manufacture of fairly large plates of from 1/4 to 1 1/2 in. in thickness. The physical properties of the metal are first discussed, following which details are given of its manufacture, beginning with the ingot phase and proceeding then step by step through stripping and reheating, rolling, flattening, inspecting and shearing, and finally, testing.*

NICKEL-STEEL plate has been employed since the early days of alloy-steel manufacture. It is used for circular saws and saw disks, structural material for bridges, etc., ship plate, protective deck plate and armor plate for warships, automobile-frame stock, etc. During the war large quantities were used as protective plate, not only for warships but for tanks, caissons, field-piece shields, etc. For many of these purposes the nickel was combined with other alloying elements, such as chromium.

In the past few years a new use has been developed for this material in the construction of steam boilers. While not strictly a new use, since nickel-steel boilers are still in service that were built over a quarter of a century ago, nevertheless the tonnage for that purpose has expanded remarkably since the use of nickel steel in 1926 by the Canadian Pacific Railway Company for the boilers of 45 locomotives. As a result of this successful application a large number of boilers subjected to high pressure have been built in whole or in part of nickel steel, and the production of this material has stimulated its use where a plate of high physical characteristics is desired, not only for boilers and pressure vessels, but for other structural purposes.

This paper deals, therefore, not with the whole gamut of nickel steels, but simply with those having between 2 and 3 per cent of nickel and no other alloying elements, such as are used for boilers, and is further confined to the manufacture of fairly large plates between 1/4 and 1 1/2 in. in thickness.

In general, however, the practice to be described is equally applicable to the manufacture of other alloy steels and other sizes. Essentially, the difference between the practice in manufacturing alloy-steel plate and carbon-steel plate is not due so much to the nickel or other alloying element contained as it is to the fact that alloy steels must be "killed" in order fully to develop their best characteristics.

## Physical Properties of Nickel Steel

While not strictly within the province of the paper, some consideration may properly be given to the physical properties developed in nickel steel. Table 1 shows the analysis and tensile properties required by a representative specification for nickel-steel boiler plate, the average results of 523 tests on such steel, and, for comparison, similar results on a carbon plate steel.

Primarily nickel steel is used because its strength is higher than that of carbon steel while its ductility is practically the same. But, in addition, the other qualities which are desirable, even necessary, in a boiler are developed with nickel steel to a higher degree than with any other material, so that it is peculiarly, almost uniquely, suited to boiler requirements.

These additional qualities are its physical characteristics at high temperatures, its excellent impact values, its resistance to embrittlement in boiler service, and its uniformity.

Physical testing of boiler materials at room temperatures and under usual conditions can at best be only an approximate guide to their suitability for boiler service. At best the working temperature of a boiler is some 200 deg. fahr. higher, in a temperature range where changes occur in the nature of the steel. But even worse, with the temperatures and pressures now being used, the steel enters the "blue-brittle" range, where an ordinarily soft and ductile metal unaccountably loses its toughness and becomes very brittle, although the strength is greater than when cold. A piece of boiler steel which can be bent double when cold will break off short at this temperature and the fracture will have the characteristic blue color which alike indicates the temperature and the derivation of the term "blue-brittleness."

TABLE 1 COMPARATIVE DATA ON NICKEL AND CARBON PLATE STEELS

*Percentage Analysis of 3 Per Cent Nickel Steel*

| | Average | Specified |
|---|---|---|
| Carbon | 0.163 | 0.20 (max.) |
| Manganese | 0.557 | 0.40–0.80 |
| Phosphorus | 0.021 | 0.045 (max.) |
| Sulphur | 0.029 | 0.045 (max.) |
| Silicon | 0.203 | Not specified |
| Nickel | 2.960 | 2.75–3.25 |

*Tensile Properties of Nickel and Carbon Plate Steels*

| | 3 per cent nickel steel Avg. 523 tests | 3 per cent nickel steel Specification | Carbon steel Avg. 385 tests |
|---|---|---|---|
| Ultimate tensile strength, lb. per sq. in. | 77,880 | 70,000 (min.) | 59,200 |
| Yield point, lb. per sq. in. | 47,550 | 0.5 × U.T.S. | 36,200 |
| Elongation in 8 in., per cent | 26.33 | 1,600,000/U.T.S. (min. 20%) | 28.64 |
| Reduction of area, per cent | 54.15 | 50 | Not determined |
| Izod impact, ft-lb. | 63.4 | ... | Not determined |

The superiority of nickel steel at these high temperatures is shown concisely in graphic form in Figs. 1 and 2[3] and only a brief reference can be made here to the resistance to corrosion and cracking of nickel steel.

## MANUFACTURE OF NICKEL-STEEL PLATE

During the steel-melting phase of the manufacture of nickel-steel plate it is necessary to use the ordinary precautions taken to insure the production of a good, sound steel, but otherwise the melting is not difficult. The nickel is usually obtained in part by charging nickel-steel scrap, such as shear scrap, and in part by the addition of metallic nickel to the charge. Since nickel is not oxidized during the progress of the heat, it is simplicity itself to hit within the specified analysis range.

Either the acid or basic process may be used, but the basic open-hearth seems to be more in favor at the present time, as the major part of the nickel steel for plates has been made on basic bottoms. The furnaces themselves are conventional in every respect, of from 50 to 100 tons capacity, and fired with oil or gas.

### The Ingot Phase

The handling of the metal in the ingot phase, important in the manufacture of any steel, is doubly so with the alloy steels, and the utmost care and minutest precautions are amply repaid later on by fewer defects and less rejections.

First, and most important, is the "killing" of the steel. Car-

[1] International Nickel Company.

[2] Metallurgist, Lukens Steel Company.

Presented at the National Meeting of the A.S.M.E. Iron and Steel Division, Chicago, Ill., November 14 and 15, 1928.

[3] For more detailed information on this subject see "Alloy Steel for Boiler Construction," Trans. A.S.S.T., 1928.

bon-steel plate generally is of the unkilled or "rimming" type of steel; that is, the silicon and other degasifying elements are purposely kept low and the metal holds in solution large quantities of gas. During solidification a portion of this gas escapes from the steel, but there still remains enough to cause in the ingot a large number of blowholes. The volume of these blowholes counteracts the voids caused by the shrinkage of the steel during

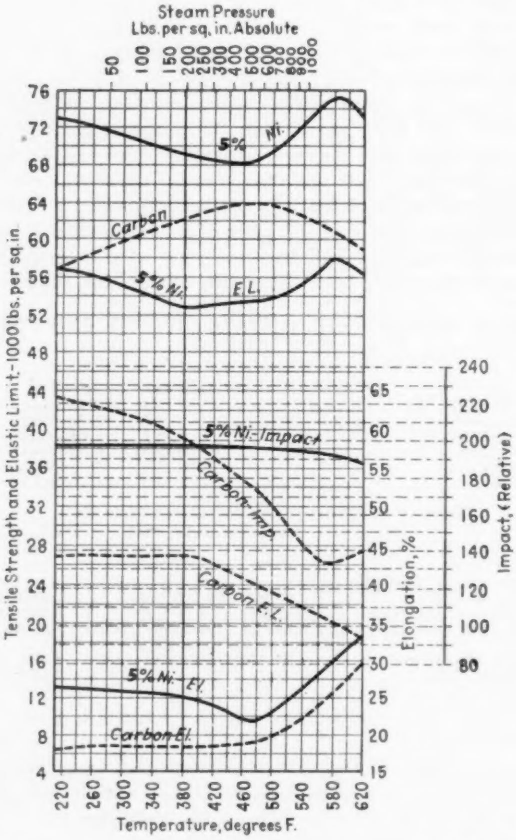

**Fig. 1** Comparative Properties of Low-Carbon and 5 Per Cent Nickel Steels at Different Temperatures and Steam Pressures

solidification, and therefore there is no "pipe" at the top center and running down through the ingot. In carbon steel the blowholes are welded up and leave little trace in the finished product of their original existence.

With alloy steels, however, such blowholes do not weld up satisfactorily. For this reason and others all alloy steels are "killed." This is accomplished by the addition to the metal in the bath or ladle of such elements as silicon, manganese, and aluminum, which eliminate most of the gases. The result of course is that the shrinkage of the molten steel causes a shrinkage void or pipe to occur in the top center of the ingot, but aside from this the ingot is sound and free from voids. In order to reduce and localize the pipe and also to insure sounder metal, it is customary with alloy steels to employ a refractory hot top on the ingot mold which, by keeping the steel hot at that point and allowing it to be the last to solidify, accomplishes the desired purposes.

Aside from the employment of the hot top, the design of the mold is most important, and the taper, wall thickness, and proportions are given careful consideration. A mold with fluted walls has recently come into favor and seems to give excellent results.

A satisfactory-sized ingot mold is 48 in. × 21 in. × 19,000 lb. An ingot from such a mold equipped with a hot top will have about 3000 lb. of metal to be discarded from the hot top.

In rolling plate by far the greatest number of rejections are due to surface defects, and an imperfection originally in the ingot surface will often persist through to the finished product. The greatest care is necessary in pouring to avoid such defects. Splashes, laps, stop pours, and mold pulls are all eliminated as much as possible. It is claimed that the process of bottom pouring, whereby a group of ingot molds are simultaneously fed from the bottom through a central downtake, results in a superior ingot surface. Such a system has, however, at least two serious objections. First are the unavoidable complications involved, such as setting up the bottom plates and runners and later removing the steel which filled them from the ingots; and second is the fact that refractory material is often cut loose from the runners by the stream of molten steel and becomes embedded in the ingot. An inclusion in an ingot resulting from such refractory material is often more serious than the minor surface defects the process is supposed to eliminate.

Therefore, while in the past bottom pouring has been largely employed, especially on deck plate of alloy steel, recently the trend seems to have been toward top pouring. When due care is taken to pour slowly and uniformly and to avoid splashes, the results have been quite satisfactory. Box pouring of two or more ingots simultaneously has given good results.

To assist in producing a good surface, mold washes are employed by some. These washes may be either the simple tar-smoke coating made by placing some tar on the mold stool or bottom, a tar or lime wash, or a wash containing flake aluminum. The latter has the dual advantage of giving a good, clean surface

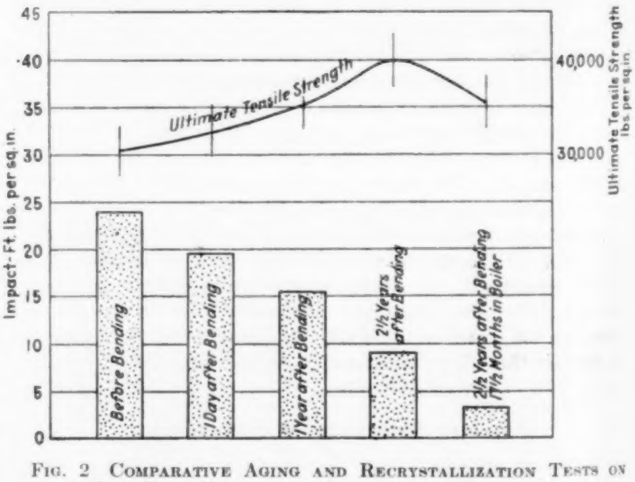

**Fig. 2** Comparative Aging and Recrystallization Tests on 5 Per Cent Nickel and Low-Carbon Boiler Steels

for the metal to lie against, as well as eliminating any small surface blowholes through the chemical action of the aluminum.

Another scheme employed by one of the largest alloy-plate producers was to place in the center of the mold before pouring a stovepipe of blue-annealed steel some 10 to 12 in. in diameter. This avoided all splashing and, as the stovepipe was melted quickly, there was no danger that it would be incorporated in the ingot.

## Stripping and Reheating

Paradoxically, large plate ingots of steel and fragile glassware require equally delicate handling after passing from the molten to the solid state. It is desirable, therefore, that an ingot should not be allowed to become cold until after some work has been done on it.

As soon as the ingot has had time to solidify throughout it should be stripped from the mold, but this should be done, if possible, where there is no likelihood of the tender outside surface, being chilled. It is preferable to remove the ingot and mold to the soaking-pit building and there strip the ingot and place it immediately in a pit.

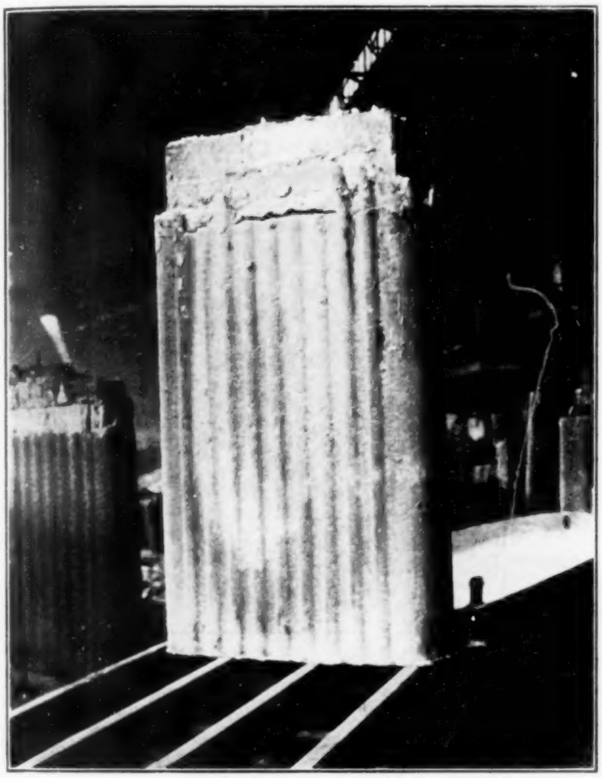

FIG. 3 48 × 21-IN. (19,000-LB.) CORRUGATED NICKEL-STEEL INGOT (C, 0.21; Mn, 0.75; P, 0.010; S, 0.020; Ni, 2.09; Si, 0.18.)

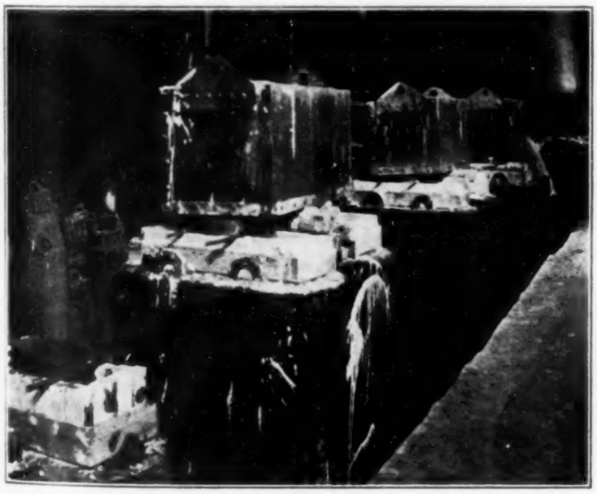

FIG. 4 MOLD SET-UP SHOWING BOX POURING OF 48 × 21-IN. (19,000-LB.) NICKEL-STEEL INGOTS

The pit should be as nearly as possible at the temperature of the ingot, and for an hour or more—for the usual-size ingot—no effort should be made to increase the heat. This time should be allowed to equalize the temperature beween the hot interior and the colder exterior of the metal. Then the heat should be gradually applied and the ingot brought up to rolling temperature slowly, using a smoky flame. If too great a heat or a highly oxidizing flame is used the original scale on the ingot will be washed off, and it will subsequently be found that it is extremely difficult during rolling to clean the plate of the second scale which forms.

FIG. 5 PLATE-TURNING DEVICE ON 206-IN. MILL TABLE

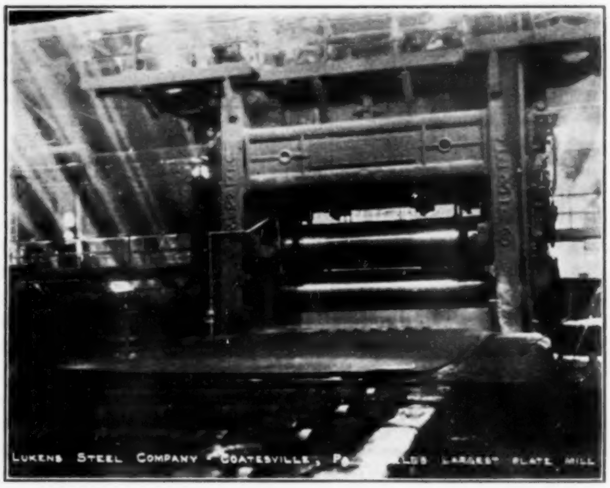

FIG. 6 206-IN. FOUR-HIGH REVERSING MILL

If it is impossible to heat the ingots immediately, they should be placed in a spare pit where they will be protected from chilling and where the equalization of heat can take place. At all events, the ingots should not be allowed to become cold.

The initial rolling temperature of nickel steel for plate should be about 2150 deg. fahr.

### Rolling

Two methods of rolling plate are in vogue; either the ingot is rolled directly into plate in one operation, or it is first slabbed—i.e., reduced about one-half in thickness—and the slabs reheated and rolled to completion, usually on another mill, but occasionally on the same one. The slabbing process has some advantages. More cross-rolling of the ingot can be done, and rolling in two directions gives better equalization of physical properties. Also, if necessary, the slabs can be allowed to cool and surface defects chipped out, after which the plate is finished. This is advantageous when rolling nickel and other alloy steels which are peculiarly liable to surface defects.

It is essential to employ some means for cleaning the plates during rolling. With carbon-steel plate water is sprayed on the plate during the latter part of the rolling, and during the last few passes salt is scattered over the surface; this causes a sudden evolution of gas as the rolls press it against the hot metal, which blows off any loosely adherent scale. Nickel steel requires more strenuous measures. In some cases coal dust has been substituted for salt, and in Great Britain broom, heather, brush, and twigs have been used. Considerable experience has shown, it appears, that the best cleaning is accomplished by the use of high-pressure water, salt, and old burlap soaked in brine. The water is directed from a series of jets at the surface of the plate as it passes through the rolls; the salt is applied at any time during the rolling and quite generously during the last few passes, while the brine-soaked burlap is thrown by men, especially stationed for that purpose, in such a way as to hit the spots which need cleaning just as the rolls strike them. Care and attention are productive of better results than is the choice of cleaning materials.

Fig. 7 Straightening Rolls of 206-In. Mill

Such methods of cleaning, used for many years in the production of protective deck plate, have had one glaring defect. They clean only the top surface, the theory perhaps being that the embedded scale will fall from the bottom surface in due time. This is not the case, and although it is not absolutely essential that both surfaces be good for deck plate, it is for boiler and firebox plate. The company which has rolled the largest tonnage of nickel-steel boiler plate has apparently solved this problem by the use of a very simple, cheap, and ingenious device with which the plate is turned over on the tables during rolling, whereby both top and bottom surfaces may be observed and cleaned.

The rolling process itself, as pursued at the plant just mentioned, is as follows: The heated ingot is first given one or two passes in a longitudinal direction, the purpose of which is to "sadden" the ingot, followed by rolling for width. When the ingot, or slab, has been broken down to about one-half its original thickness and to a size suitable for recharging into the soaking pits, it is removed from the mill and allowed to cool prior to inspection. It is then chipped with pneumatic chisels to remove serious surface defects, although in many cases it is taken to the machine shop and the entire top and bottom planed off. This drastic and rather expensive treatment has seemed in many cases to be justified by the eventual results.

Fig. 8 3 Per Cent Nickel Steel as Rolled. × 100
(Specimen taken from a 273 × 145 × $^{12}/_{16}$-in. front barrel sheet.)

Fig. 9 Same Steel as in Fig. 8 After Normalizing. × 100

The cleaned slabs are carefully reheated and finish-rolled on a four-high reversing-type mill. When the plate has been subjected to the heavier drafts and after the top surface has been cleaned by the use of burlap and salt, it is run into the apparatus set in the table and turned over so that the bottom surface can be cleaned and rolling completed.

### Flattening

Ordinary carbon-steel plate exhibits such a slight tendency to harden when cooled rapidly that the finishing temperature

of rolling and the quenching effect of the flattening rolls make comparatively unimportant changes in the tensile properties of the metal. Alloy steels are quite different, and important effects can be obtained by varying the finishing temperature and the rapidity of cooling.

Generally speaking, the best combination of physical properties is obtained with nickel-steel plate if it is not cooled through the critical range too quickly. For that reason it is well to plan on finishing actual rolling at a good red heat (1450–1500 deg. fahr.) and allowing the plates to cool slowly through the critical range on the cooling bed by piling one plate on top of another or by taking them off the beds, piling and covering with sand, and then restraightening.

There is a growing conviction among plate users that plates, even of carbon steel, should not be used in the "as rolled" condition, and that principles of safety and efficient use dictate a normalizing of plates prior to use. It is not known that this heat treatment is being given, except sporadically, by any mill, but it seems to be accepted that sooner or later all plants will be equipped with furnaces sufficiently large to heat-treat all plates. Both the manufacturers and users of alloy-steel plate will be benefited by such a change, though it must be admitted such practice would be more of the nature of a refinement than a necessity. In this connection it is of interest to note that the plates of nickel steel for the latest locomotives were ordered by the railroad to be normalized after rolling.

The gage of the plates has also an effect on the hardening, and for that reason the lighter-gage plates are somewhat lower in carbon than the heavier ones. The thinner gages, finishing colder, would for the same analysis give higher tensile values, so that the minimum tensile strength possible with a 2.0 to 3.0 per cent nickel steel would still be considerably higher than for a corresponding carbon steel.

### Inspection and Shearing

When inspecting alloy-steel plates, the defects to look for are "snakes" and pits or heavy embedded scale. Well over 50 per cent of the necessary rejections will be for these causes.

The reason for the existence of pits and scale are apparent, but why snakes appear is still, the authors frankly confess, a mystery. Any theory is good until it fails to be supported by facts. So far no specific cure for them has been found, and it would seem they are simply in the nature of a disciplinary dispensation to keep the steel maker from finding his career a bed of flowery ease. The use of great care during the pouring of the ingot and the avoiding of sudden drafts on the ingot just after it has been stripped seem to have a beneficial effect in this regard.

The only method of dealing with snakes, when they occur, is to grind them out. This practice has been permitted by the United States Navy for a number of years, and while it is still not acceptable to some purchasers, it seems to be an unnecessary hardship on the steel mill to be forced to reject plates which are otherwise good. The recommended method of grinding, if the snakes are not too long, is to use an abrasive wheel of a diameter sufficiently great that the trough or groove so ground will not have sharp corners. To be sure of removal, the clean ground surface should be etched with acid (hydrochloric 1–1 in water is good) to develop any remnants. If no trace of the seam remains after this treatment and the plate is not reduced in thickness beyond permissible limits, it should be considered good delivery.

Pits and scale marks are left to the discretion of the inspector. If serious or too frequent, they are cause for rejection; if only occasional and of slight depth, they may be accepted.

It is at this point that the fact that alloy steels are killed steels is first apparent. The pipe in the top of the ingot, unless the slab was cropped, still occupies the same proportion of the plate, and this portion must be rejected. This is the reason for the comparatively low yield on alloy-steel plate. With the rimming" carbon steel there is no pipe, and the percentage of usable product to total weight will run in the neighborhood of 70 per cent. With alloy steels this ratio will be nearer 60 per cent. In both cases, of course, the side and bottom shear scrap is the same.

It often requires considerable ingenuity on the part of the layer-out to fit his sketch on a plate and avoid on the one hand the pipe and, on the other, whatever surface defects there may be.

### Testing

The usual tensile tests are required, which include longitudinal tests from various parts of the plate as well as a top transverse

Fig. 10 Full-Bend Test on 3 Per Cent Nickel-Steel Boiler Plate

test. The majority of specifications call for the tensile values to be determined from a bottom longitudinal specimen and the bending properties from a top transverse specimen. It might be well to point out the difference between the tensile tests in a killed alloy steel and a rimming or open steel. The former, due to being killed, is very uniform, showing little difference between the tensile test taken from the top and that taken from the bottom, as well as little differences between the transverse strength and the longitudinal strength. The open steel, however, which is from its nature a segregating steel, will show considerable variations between the top and bottom tensile tests, as well as between the longitudinal and transverse tests. By the same token, the variation in analyses of the nickel steel between any two parts of the plate or ingot is very much less than in carbon steel, which results in a more uniform product.

Microscopic examination is rarely called for. The main defects which show up under such examination are laminations and large grain. The latter is due to high finishing temperatures, and is of no importance if the steel successfully passes the tensile and bend tests.

Laminations are of two kinds. The first is due to a segregation of the pearlite and ferrite constituents of the steel into layers, and is quite common in all plates. It is probably due to the unidirectional work done on plates and is rarely a serious defect. The other is an actual separation of the metal and is usually caused by incomplete cropping of the plate, so that a portion of the pipe remains.

### Conclusion

Emphasis has been placed throughout this paper on the defects occurring in the manufacture of nickel-steel plates, but which, for that matter, are common to all alloy-steel plates. The danger is that this emphasis will give the false impression that such plates are difficult to make and of doubtful reliability.

Such is not the case. Without going further, the subject has been briefly summed up by one of the largest users of nickel-steel plate, who reported that the surface of the nickel-steel plate delivered to him was the equal of that of carbon-steel plate, and stated that, disregarding the alloy entirely and comparing them on an equal basis, the nickel-steel plates were better than the carbon-steel ones used at the same time, and that there were more rejections of carbon steel than of nickel steel. This, however, is not meant to imply that the purchaser should expect a better surface on nickel steel than on carbon steel.

## Discussion

W. J. MacKenzie.[4] Experience has taught us that high-grade alloy steels of today are possible because each and every operation from the selection of the charge, the melting, refining, pouring, heating, rolling, etc., has been carefully studied. However, many problems are still without a definite answer. For example, today for the first time a real study of slags, their composition, reactions, etc., is being made. Up to this time we have only known their general behavior. Further, there are the unknown constituents of steels, the so-called dissolved gases, the nitrides and oxides. The writer believes the day is not far distant when we shall be able to explain the different dynamic results obtained on different heats of the same chemical analysis by a more intimate knowledge of the chemistry of these oxides and nitrides, and shall be able to state which are harmful and which are not.

In the paper mention is made of a satisfactory ingot mold for plates, which is 48 × 21 in. and casts an ingot weighing 19,000 lb. The statement follows that the hot top on the ingot will contain about 3000 lb. of metal. Then later it is stated that the usual yield on alloy plates is about 60 per cent. In a conversation the writer had with Mr. McKnight he pointed this out and explained that in this 19,000-lb. ingot more than 3000 lb. of hot top is discarded to get to sound steel. Or, if only the hot top were discarded the yield would be 84 per cent instead of 60 per cent. This leads the writer to wonder why larger hot tops are not used, and if the ingots are poured with the big end up or down. For our purposes the big-end-up mold seems to work the better, and our hot tops are sufficient to take care of all piping and segregation.

Some mills roll their alloy plates direct from the ingot, while others double-convert. We double convert all our bar stock that we furnish in rounds, squares, and flats. The ingots are rolled into billets, which are pickled and chipped. They are then reheated and rolled into the finished bar form. Pickling is especially helpful to us because it shows up all surface defects, which sometimes cannot be seen through the scale, and this is particularly true of the nickel steels because of their greater tendency to scale. The writer wonders if pickling the billets or slabs for plates is employed.

In conclusion, the writer is glad to note the interest being shown in alloy steels for high-strength work other than automotive. They have a definite place, and will find an ever-growing field for their application. The steel mills are all glad to help on any problems presented, and maintain large staffs of metallurgists for this purpose.

William A. Newman.[5] Just what practical results the Canadian Pacific Railway Company has obtained with the use of nickel-steel boiler plate may be of interest.

Early in 1926, when we decided that we would increase our standard boiler pressure from 200 lb. to 250 lb., we anticipated that our boiler maintenance would be more difficult and expensive, but were willing to accept the more adverse circumstances in view of the greater capacity and efficiency that could be obtained by the use of higher boiler pressures. Forty-four locomotives were constructed during 1926, and somewhat to our surprise the increased maintenance difficulties have not developed; in fact, our 250-lb.-pressure locomotive boilers constructed of nickel steel actually gave less trouble through leaks than is the case with boilers carrying the maximum pressure of 200 lb. per sq. in.

During fabrication nickel steel is no more difficult to drill than carbon steel, but is naturally somewhat stiffer to roll. There is necessarily a certain amount of hand flanging in a locomotive boiler in order to set up portions of the boiler tightly in contact with the adjacent plates or foundation rings, and we do find that it is much harder to set nickel steel than it is carbon steel. Once the plate is set, however, it stays that way and this is also true of calking the plate, it being slightly harder to work; but as was stated for the flanging, once the material is worked to its final position it remains that way, to which, of course, we attribute the excellent service that we have had from our boilers in that they have not developed the minor leaks, etc., that all locomotive boilers are more or less addicted to with the constant working and vibration to which they are subjected.

Altogether from early in 1926 up to the present the Canadian Pacific Railway Company has put into service 72 locomotives, including two locomotives operating under 275 lb. pressure, in which nickel steel has been used for all the main-course plates and also to a certain extent for tube sheets, firebox, and wrapper sheets. The use of nickel steel was of course purely experimental, and was our answer to the increasing difficulties of building large locomotives and keeping them within weight limitations. Our experiment has been successful in every way so far as the actual fabrication and operation of boilers is concerned, and incidentally the weight saving that was effected in boiler plates amounted to approximately 28 per cent.

C. A. Seley.[6] The entry of alloy-steel plates into steam-boiler designs, particularly those of locomotive boilers for railway use, has mainly been brought about by weight considerations in connection with large-capacity requirements in railroad service. The higher tensile strength afforded has permitted an increase of steam pressure without proportionate weight increase.

The C. P. R. locomotives as quoted in the paper carry 250 lb. steam pressure as against 200 lb. for approximately similar boiler designs built of carbon steel. We hear of somewhat higher pressures being employed in stayed-plate locomotive boilers up to 275 lb. and possibly to 300 lb.

Quoting from the fourth paragraph of the second page of the paper: "With the temperatures and pressures now being used, the steel enters the 'blue brittle' range, when an ordinarily soft and ductile metal unaccountably loses its toughness and becomes very brittle, although the strength is greater than when cold." As stated, an unsafe condition is entered into when steam temperatures approximating those of the so-called "blue brittle" range are employed with the use of carbon steel.

In the C. P. R. boilers mentioned, alloy steel was used in the shell and outer sheets, which were not increased in thickness over previous designs. These sheets are swept by the steam and water and the temperature of the 200-lb. saturated steam, as formerly used, was 388 deg. fahr. That of 250-lb. is 406 deg., an increase of 18 deg. or 4.5 per cent for a 25 per cent pressure increase. If

[4] Vice-President, Interstate Iron and Steel Company, Chicago, Ill.

[5] Chief Mechanical Engineer, Canadian Pacific Railway Co., Montreal, Canada.

[6] Consulting Engineer, Locomotive Firebox Company, Chicago, Ill.

we go to 300 lb. it requires a further addition of 14 deg. or 422 deg. fahr. steam temperature.

The word "brittle" is ordinarily defined as "easily broken, apt to break, fragile, not tough, or tenacious." One would infer from the language of the paper that the steel as ordinarily applied in our boilers becomes brittle in some of the above senses with even moderate increases in pressure and temperatures.

The writer finds it difficult to accept the conclusion in the paper on this feature, even while assuming all the possible advantages set forth in favor of alloy steel.

We are all aware that steel properties vary with temperatures and that the tests as outlined in various specifications are to be made at normal room temperatures and that a so-called factor of safety, or more appropriately, perhaps a factor of uncertainty is used in design. Some have been forthright enough to call it a factor of ignorance.

If alloy steel is used for firebox material, there is a somewhat greater range of temperature of the sheets exposed to fire. If the surfaces are clean the resistance to the passage of the heat through the plates is very small indeed. A resistance is built up with scale on the water side, adding somewhat to the sheet temperature engaged in the transfer of heat to the water, and upsetting all the scientific deductions by the extreme variability of thickness and resistance to heat conductivity which is affected thereby.

Thus is permitted a further excursion into the "blue brittle" range of temperature, of an entirely unknown and variable amount, for the firebox sheet, rendering it more and more brittle and unsafe, if the language in the paper is to be accepted as stated.

Nevertheless, and notwithstanding, more or less of the 70,000-odd locomotives in the United States have thus been operated these many years in an unsafe condition, although not evidenced by failures that can be traced to operation in the "blue brittle" temperature range.

We all know that firebox sheets crack and fail miserably sometimes, but it is plain to engineers that the locomotive boiler is the most abused steam generator in use, particularly in its terminal handling, where probably 90 per cent of the general maintenance—listing as such, cracks, leaks, sheet renewals, broken staybolts, etc.—is initially caused by stresses set up in terminal handling and not in normal operation.

Any development and improvement in boiler metals that will have a tendency to minimize the effects of these conditions is surely very laudable and worthy of most serious consideration of this and other engineering societies.

Leon Cammen.[7] Several discussers have made reference to leaks on locomotive boilers. Such boilers leak because the rimmed steel of which they are made is steel which contains gases, chiefly carbon monoxide, at the time it is being chilled. The result is that the steel is full of small bubbles, which, contrary to the statement of the authors, are not squeezed out when the steel is rolled, but are changed in shape. Because of the presence of carbon monoxide the surfaces of these bubbles are not oxidized. If there were any oxidation the carbon monoxide at that temperature would immediately convert itself into carbon dioxide. The bubbles cannot weld 100 per cent without dissolving the carbon monoxide, which of course is impossible. Therefore a bubble will weld up to about 90 per cent perhaps, the remaining 10 per cent being a tiny cavity filled with gas under very considerable pressure.

The action of this tiny bubble with reference to shocks, and particularly to vibrational stresses, is exactly the same as would be the action of a notch in a piece of steel. In other words, a plate of rimmed steel contains throughout its body a series of spots so arranged that the development of stress, strain, and failure is predetermined by the shape and direction of the bubble. Sooner or later it will begin to crack, and if several such bubbles happen to be located one next to the other across the thickness of the plate, a leak will result.

The nickel steel described in the paper is a killed steel, or one which is thoroughly degasified. There is no carbon monoxide in it at the time the steel sets, and therefore it is not so subject to leaks and gives less trouble than ordinary plate steel. If we took the same pains and made the carbon steel a killed steel, it would probably be free from bubbles and at least as free from leaks if not as strong as the nickel steel. It would, though, have a greater tendency to oxidize than does nickel steel.

# Rolling-Mill Lubrication

By L. P. Tyler,[1] Pittsburgh, Pa.

*The author confines his discussion to those modern installations where lubrication is effected by means of a system which automatically circulates a single lubricant. He first considers the mill members best adapted to such lubrication, following which he outlines the conditions to be satisfied for correct lubrication. The requirements to be met by the lubricant are then enumerated, and instructions are given for its application and handling. Finally the advantages of such a system in the way of economy and in the compactness of design it permits are pointed out.*

PROBABLY no industry offers the variety of problems to test the skill of the lubrication engineer than does the iron and steel industry. Rolling-mill machinery, in particular, presents many unusual problems of lubrication because of the severity of service under extremely unfavorable operating conditions.

Oils and greases should be carefully selected to meet the variety of operating pressures, temperatures, speeds, and contaminating influences of dust, dirt, scale, and water to which they will be subjected on the various types of rolling-mill equipment.

In addition, it is important to select a method of application which will provide continuous film formation with the proper lubricant at maximum economy and with due regard to safety and conservation of the operator's time.

Equal care must be exercised in conditioning oil which is re-used, and in its handling and storage, to preserve the original purity and cleanliness of the lubricant for as long a period as possible.

The application of these principles to the definite problem of the lubrication of modern rolling-mill driving equipment will now be considered.

In recent years the general introduction of the electric drive has effected some very marked changes in the rolling of steel. Changes in methods of rolling have altered the power requirements, increasing the loading and mill speeds so that mill tonnages today are much greater than they were ten and even five years ago. The art of rolling steel has usually led and seldom lagged in the advances of the iron and steel trade. From 1783, when Henry Cort obtained his patents for puddling iron and rolling it into bars, the design of machinery has steadily improved, both in power and accuracy. At no period probably have these advances been so rapid as within the past five years.

The purpose of this paper is to indicate how the science of lubrication has fitted into the scheme of progress. Probably in no other industry is the necessity for continuous operation of more importance; and in no other is there greater loss as a result of forced shutdown. Increase in the size of ingots rolled, the development of high-speed motor-driven continuous mills, and greater competition in the steel market have further enhanced the value of reliability as well as operating economy.

Continuous operation at minimum cost per ton is the result sought. Many forces militate against this objective, such as roll changes, short orders, furnace operation, mill breakdowns, and repairs. Correct lubrication as a factor in maintaining continuous operation is therefore of great importance. The automatic features of the modern mill have substantially reduced the cost of operating labor. It is therefore desirable that the auxiliary features which serve the main purpose shall assist in economical developments.

[1] Vacuum Oil Company.

Presented at the National Meeting of the A.S.M.E. Iron and Steel Division, Chicago, Ill., November 14 and 15, 1928.

Discussion will be confined to those modern installations where lubrication of reduction gears, mill pinions, and their bearings is being secured with a single lubricant applied by an automatic-circulation oiling system. Those members of the mill which, in the author's experience, can be served by a system of this sort would include those mentioned in the following paragraphs:

## Mill Members Best Adapted to Lubrication by an Automatic-Circulation System

*Pinions and Their Bearings.* The function of the pinions is to divide the power supplied by the motor through a single shaft or spindle among the rolls and to control their direction of rotation. Their shafts run in plain bearings contained in the housings. In the oldest form the pinion teeth ran straight across the face, but later it was found that smoother operation resulted from dividing the face into two parts and staggering the teeth of the two halves. Today pinions are made with helical or "herringbone" teeth, and are accurately machined and generally heat-treated. This tends to materially reduce vibration inasmuch as some parts of the teeth are always in contact and transmission of the power is continuous. It also permits much higher peripheral speeds. Pinion speeds are likely to vary from 10 to 500 r.p.m. and higher. A typical high-speed pinion on a strip or skelp mill will have a pitch diameter of 12 to 14 in., a face width varying from 20 to 28 in., and a circular pitch of approximately 2 in. At the other extreme a typical pinion for a large blooming mill would be approximately 60 in. long between the necks, and have a pitch diameter of 40 in. and 14 teeth.

Early lubrication practice was to give the pinions an occasional dressing of pine tar, plumbago and tallow, or other mixture of grease. This practice was followed later by having the housings cast in one piece so as to form an oil bath in which the bottom pinion was partly submerged. This has in turn been followed by the present practice of spraying a heavy-bodied oil under pressure to the teeth at the line of mesh.

The design of the pinion bearings has likewise undergone some very decided changes. In the early stages these bearings consisted of babbitted cast-iron shells with pockets cored for the storage of grease for the lubrication of the journals. The advent of cut-tooth pinions necessitated a greater degree of accuracy in the mounting and alignment, as well as more efficient means of lubrication. It was generally believed that a heavy oil or gear shield was necessary for the pinion-tooth lubrication and a lighter oil for the bearings. This necessitated a design which would separate the two lubricants, a rather difficult task. To overcome this, oils have been provided for the lubrication of pinion teeth as well as the pinion journals. The use of a single lubricant for both pinions and bearings simplifies the design and saves 10 to 12 in. in the length of the pinions. Babbitt is used as a bearing metal on practically all installations.

*Reduction-Gear Drives.* The present high-speed mills have introduced accurately cut single- and double-helical reduction gears in single or multiple reductions, serving one or more roll stands. The horsepower transmitted will vary from 500 to 5000.

The bearings for the gear drives are generally of the ring-oiled type, although roller bearings have been used on a number of recent installations. Here again the bearings were, until recently, designed for the use of lubricants on the gear teeth different from those on the bearings. The use of a single lubricant permits simplification in design with a material decrease in bear-

ing centers, which latter is important in the elimination of shaft deflections.

*Roller Bearings on Roll Necks.* The recent progress made in the application of roller bearings on the roll necks of rolling mills and also on pinion stands is worthy of note. Their correct lubrication is simpler and much more economical than the former design. Owing to their location it is not always desirable to tie in the roll-neck bearings with the oiling system serving the gears and pinions. Experience has shown that where they are subjected to severe washing action the water is readily carried into the system on oil-lubricated bearings. This may later be overcome by improved sealing arrangements.

### Correct Lubrication as Related to Present Problem

Correct lubrication results from the complete and continuous separation of the rubbing surfaces of the gears, pinions, and their bearings by an oil film of sufficient strength to resist the pressures, with minimum fluid friction. There must be arrangements for a continuous supply of clean, cool lubricant of the proper quality without waste.

Correct lubrication as related to the present problem must satisfy the following conditions.

1 *Reliability in Terms of Permitting Full and Continuous Production.* There must be assurance of a sufficient supply at all times of the proper lubricant to permit normal operating temperatures of gears, pinions, and their bearings. The mechanical features of the system itself should introduce no elements in which breakdowns are likely to occur.

An important advantage, as noted above, resulting from the use of a single lubricant is the elimination of the danger of contamination of the gear lubricant with the bearing lubricant, and vice versa. There is always a tendency for this transfer regardless of the care exerted by the manufacturer in sealing the bearings and equipping them with slingers and oil-drain grooves.

The frictional heat developed between the meshing teeth of the gears spreads to the bearings and gear case. Where a circulating oiling system is not employed, all of the heat developed must leave by radiation from the gear case. The difference between the temperature of the gear unit and that of the room is termed "frictional temperature." Gears operating at high speeds and lubricated by the splash of heavy oils often develop heat so rapidly that the frictional temperature becomes excessive. Under such conditions a circulating oiling system permits a flow of oil to the gear teeth, and the oil therefore becomes a coolant as well as a lubricant, radiating the heat to the atmosphere in its passage through the system.

The ring-oiled bearings of the drives are in effect a miniature automatic-circulation oiling system. Their limitations are the small volume of oil in service and inability to control the rate of feed. In large-size, high-speed, and heavily loaded bearings the pumping capacity of the rings may be less than that required to assure normal operating temperature. The modern system of lubrication offers a means of

(*a*) Changing the oil automatically and continuously
(*b*) Maintaining a constant level
(*c*) Varying the feed to meet the operating condition.

These result in a supply of clean and cool oil in sufficient quantity to maintain a strong supporting film, and also act as a coolant.

2 *Maximum Life of Equipment.* With the older machinery, frequent replacements were necessary and were not so expensive; but with the higher cost of new machinery, replacements are costly and shutdowns seriously interfere with production. The continuous action of supplying and withdrawing a fluid lubricating medium to and from the gears, pinions, and their respective bearings, permits the immediate removal of dust, mill dirt, scale, and other solids which act as abrasives, producing rapid wear.

3 *Lower Operating Costs.* Under this item should be considered the smaller consumption of power and the reduction in oiling labor and in the cost of lubrication. The rapid absorption and removal of heat by a cool fluid lubricant, together with minimum fluid resistance, produces low operating temperatures and maintains the proper alignment of the machine parts. This assists materially in the reduction of frictional losses and therefore permits high operating efficiency.

It is a well-known fact that the movement of the roll necks in their bearings, the pinions and their bearings, the driving gears and bearings as well as spindles, couplings, etc., imposes a very considerable frictional resistance, depending upon the design and operating conditions of the mill. Numerous tests have been run with the desire to determine exactly the power required to roll steel of various sections, and also to determine the frictional resistance of the moving parts. Reliable tests show, for instance, that the total power developed by a reversing-mill engine is distributed about as follows:

| | Per cent |
|---|---|
| Actually deforming the steel | 30 |
| Overcoming idle friction of the engine parts | 27 |
| Overcoming roll-journal friction | 13 |
| Overcoming acceleration of the parts in reversing | 21 |
| Overcoming pinion and spindle friction | 9 |

The development of roller bearings capable of sustaining the loads involved has of course materially reduced the power required in overcoming roll-neck friction. On continuous mills the power generally required in overcoming pinion, gear, and spindle friction runs from 12 to 15 per cent of the total power delivered. Recent tests on modern strip mills, oil-lubricated and equipped with the latest refinements, indicate a power requirement of about one-half that used in ordinary strip mills of corresponding sizes. An additional factor is the elimination of any undue starting torque, particularly in cold weather.

The cost of labor in attendance on a well-designed modern system is very small, the requirements being merely periodic inspection of the various oil-flow indicators, thermometers, gages, etc.

Due to the care exercised by the manufacturer in the design of bearings as well as gear and pinion housings, the mechanical losses of oil are practically nil.

### Application and Handling of the Lubricant

Primarily the lubricant is applied by means of a circulation oiling system. The system consists essentially of

1 A main supply line with branches to the various elements to be lubricated
2 A common return line into which drain the individual returns from each element
3 A suitable return tank to rest and cool the oil, and separate the heavy impurities and water
4 A means of cleaning and purifying the oil and pump
5 Clean-oil storage capacity.

The oil is applied to the gears under a pressure of 20 to 30 lb. per sq. in. by means of properly designed spray nozzles. These nozzles deliver the oil to the gears close to the line of mesh so that at the moment of contact the gear teeth are generously supplied with lubricant. The oil to the pinions is supplied at the top of the housing and cascaded into the engaging teeth by means of baffle plates suitably arranged. Suitable regulating devices permit control of the oil flow, and sight-flow indicators enable the operator to detect at a glance the quantity of flow. Suitable return piping drains the oil from the bottom of the gear case or pinion housing into a large return tank. Supply lines and regulating sight-feed oilers also furnish clean, cool oil to the

bearings, and the oil is returned from the bottom of the bearing reservoir to the return tank.

After the oil has done its work it should be given a short period of rest. This is for the purpose of dropping out solid impurities and water. This is accomplished in the return tank, the size of which depends of course on the volume of oil which it is necessary to circulate.

Additional cleaning is given the oil by some arrangement for bypass purification intended to assure the thorough and complete removal of water and insoluble impurities.

A clean-oil supply tank is used to store the conditioned oil and to assure a generous supply of lubricant at all times. This also permits the oil to cool, thus maintaining its original viscosity.

### Requirements to Be Met by the Lubricant

The problem of selecting the proper lubricant for steel-mill drives is basically composed of the following factors:

1 The lubricant must possess sufficient body to establish a film on the working surfaces of sufficient strength to resist rupture by the unit pressures imposed. These pressures are most severe on the engaging teeth of the pinions because of the shock loads to which these parts are subjected. An examination of the power-load curves on the motor drives indicates this feature, in addition to which the energy given up by the revolving masses must be considered. There are variables such as draft, temperature of the material, roll condition, etc., which make it extremely difficult to calculate, even on similar mills, just what this condition of maximum loading on the pinion teeth will be. It is therefore logical to select an oil which, by its body and adhesive characteristics, offers the maximum factor of safety against film rupture.

This consideration is particularly important in selecting an oil for the lubrication of the driving equipment for the modern continuous wide-strip mills. The mill builders emphasize the desirability of exact equalization of working-roll diameters to prevent slippage between the rolls and the metal or within the metal itself. With unequal roll diameters the spindle torque and the pinion tooth pressures may be sufficient to cause rapid pinion wear. This is particularly true in rolling wide, thin material, and on these mills the requirements for pinion lubrication call for an extremely heavy-bodied oil.

At the same time, a liberal proportioning of the pinion face with the resultant reduction in unit tooth pressure is highly desirable.

In this connection it is very seldom found that the oils selected are too heavy to take care of the bearings properly, inasmuch as the working clearances generally allowed are sufficient to accommodate these oils under working temperatures.

In addition to its function as a lubricant, the continuous washing of the gears and pinions with a cool, fluid lubricant maintains clean contact surfaces and results in a cooling action.

2 The lubricant must be adaptable for use in a circulation system. This circulation system involves the constant use of the same quantity of oil. It is therefore obvious that a properly selected, carefully manufactured oil will result in the greatest degree of dependability and economy.

The natural enemies of lubrication which the oil must combat are heat, air, water, and solid impurities. Air and heat cause a certain amount of oxidation of the oil, forming products, some of which are soluble and others insoluble. Water combines with products of oil oxidation and other foreign impurities to form emulsions in the oil. These factors are overcome by (*a*) the use of a high-quality oil possessing maximum chemical stability, (*b*) by provision for the removal of water and solids by heating, settling, and cleaning, and (*c*) by the reduction of soluble oxides by cooling and settling.

Where water is a factor, the roll-neck roller bearings should be separately lubricated by a good grade of grease of the proper consistency. Sufficient pressure should be applied to the grease to maintain a very small leakage from the seals so as to prevent any infiltration of dirt, scale, or water. It is also desirable to remove these bearings periodically and give them a thorough cleaning with light oil.

### Conclusion

The present systems which have been applied to blooming- and universal-mill pinions and bearings, as well as the drives, pinions, and bearings of continuous mills, are the outgrowth of the demand by both the steel-mill operators and equipment builders for a lubrication service which would meet modern mill practice. The last word has not by any means been said. Improvements in the design, manufacture, and placement of the machine parts, as well as in roll construction, temperature control, etc., will result eventually in the use of lighter-bodied oils than are employed at present, with the improved economy which this involves.

The ultimate economies from the use of a single lubricant are not all confined to operation. The practice permits of compact design, smaller gear and pinion housings, and the elimination of elaborate bearing seals and grooving.

In conclusion, it may be stated that the lubrication of modern high-speed mills is of great importance, has possibilities for substantial economies, and is worthy of the most careful thought and planning.

## Discussion

E. A. Franke.[2] In the lubrication of journals on locomotives we have been using a soap grease which is half soap and half oil. We have had trouble from the failure of locomotive axles due to the high operating temperature. Tests show this to be in excess of 400 deg. fahr. What has been the experience of the author with grease on heavy machinery?

W. D. Hodson.[3] We have specialized on mill work, and we question the possibility of making one type of lubricant function properly for all kinds of loads, speeds, temperature conditions, etc. We have found it necessary to use three different types and to use different consistency numbers for each type.

S. M. Weckstein.[4] In September, 1927, we installed what was the first large anti-friction reduction unit. It was 1500 hp., 350 r.p.m. The pinion bearing was 12 in. and the gear-shaft bearing was 17 in. The gear bearings were lubricated with 600-W oil. That unit has been working ever since, and there has been no trouble whatever.

On October 4 of this year we installed a new 28-in. mill, and the gear unit used is a 2000-hp. drive, 350 r.p.m. We felt it would be advisable to have the bearings lubricated separately from the gears and so worked out a system of lubricating the gears with 600-W and lubricating the bearings with a separate circulating-oil system. The oil pump is mounted on the gear shaft. It takes considerable time after starting for the bearings to become properly lubricated, and a lubricating system with a separate pump is preferable to a pump driven from the gear shaft. In any case a level should be provided in the bearing chambers for the oil. The bearings installed were large Timken bearings. They are run at high speeds, and it is very necessary that the lubricant be sent to the bearings at a good rate of feed and high pressure in order to keep them cool and clean at all times.

[2] Chief Chemist, Rock Island Lines, Chicago, Ill.

[3] Hodson Corporation, Chicago, Ill.

[4] Timken Roller Bearing Co., Canton, Ohio. Mem. A.S.M.E.

Where water conditions are encountered it is impossible to use oil. In those cases we use grease and force the grease through the closures so as to keep the water out. We are working out a special air seal now which we believe will keep the water out so that it will be possible to use oil.

LOUIS F. COFFIN.[5] The paper should spur on the adoption of the one-lubricant drive, and steel-mill operators should agree with the author that the death knell of the gear shield-bearing oil combination has been sounded for major mill drives. There are several important considerations that should shape the trend of this development. Accuracy of tooth contour and of bearing alignment must be given more attention so as actually to distribute the load over at least three-fourths of the tooth face instead of only one-fourth or one-half as is now too frequently the case. Gear and pinion material of sufficient hardness to give a long life is essential in order to justify the expense of the automatic one-lubricant oiling system. The author is quite optimistic when he states that "mechanical losses of oil are practically nil." Many manufacturers have much to accomplish in improved sealing devices, adequate oil pans, drain connections of ample size with proper vents, etc., before such drives may be considered oil tight. This fact is a serious present deterrent to more widespread use of oil for mill drives. Also in many installations, mill-water sprays are apt to strike the gear or pinion drives, and more protection from this contaminating influence is needed. The tendency toward using a heavier and heavier bodied oil seems to be in the wrong direction. A very heavy oil, say of 1500 to 2000 seconds viscosity at 100 deg. fahr., as also with a good gear lubricant and in most cases a good bearing lubricant, has the unfortunate property of not separating from water and dirt and scale as rapidly or as entirely under mill-operating conditions as an oil of 500 to 1200 seconds viscosity. Continued purity of the oil is essential and can be much more easily obtained with the latter oil. On account of this, mill main gear and pinion drives should be designed to use an oil within the latter ranges. The use of the pressure spray is of course to be considered the major means of lubricating gears in such drives, as well as the cascading baffles, but in certain slow-speed drives these, together with a bath, are often advisable. While reduced labor cost in operating such systems is generally to be expected, more intelligent supervision is, however, required.

### AUTHOR'S CLOSURE

In regard to what Mr. Franke has said, in many cases the type of grease used is dictated by the design of the bearings. For instance, on the roller bearings used on conveying tables we are using a lime-base grease of about No. 2 consistency, and in places where it is subject to severe heat conditions, a No. 3 grade grease. These are applied mostly by pressure fittings.

Due to the heat from the material passing over the rolls, the journal temperatures run as high as 200 deg. fahr. The ordinary type of lime-base grease which is adaptable for pressure feeding is not adaptable to those high temperatures because it turns to a thin fluid so easily, so we have reverted to a sponge type of grease or what might be called by the chemist a soda-soap grease, which has stood up well at these temperatures. In cement mills it has always been customary to use grease, and oftentimes the grease which has come in contact with the shaft becomes very severely charged or hard and caked; in other words, the oil content has been withdrawn and the grease has become useless. Correct heavy-bodied oils have improved the lubrication.

The same thing is true in a steel mill. Where there is considerable frictional heat and heat radiated from the material and where grease has been used, we have gone to very heavy cylinder oil and applied it mechanically in small amounts. And by using a cylinder oil that will stick on the journal shaft and by automatically controlling the rate of feed, we have improved the life of the bearing metal many times and lessened the cost.

From what Mr. Hodson has said, some may have gathered the impression from the paper that one oil is desirable for all types of equipment. That is not true. Nor is it true that we advocate the use of oil on all types of mills, regardless of the design or regardless of the speeds, temperatures, and pressures encountered. We manufacture a range of oils which we have found have worked out on various types of equipment, and where we have been in doubt as to the pinion pressures or tooth pressures that were to be encountered we have found it better to use as heavy-bodied a lubricant as could satisfactorily be circulated. Where the mechanical design is such that oil losses are not preventable and held within a range, we believe the use of a heavy-bodied grease is desirable. On the other hand, the advantages from the standpoint of a single lubricant we believe are very important.

On a large strip mill which is now being installed by the Wheeling Steel Company at Steubenville and which is to roll strip 60 in. wide, the pinions will be connected to a special system for handling a heavy-bodied oil under pressure. We do not feel that the reduction gears necessarily require an oil of this body, so that a separate system will be used for the lubrication of reduction gears and their bearings.

One of the first installations was at the Bethlehem Steel Company on the four Gautier mills which were put in four years ago. The 10,000-gal. oiling system used serves the Morgan pinions, reduction gears, and bevel gears. The Weirton Steel Company at Weirton, W. Va., has a 48-in. continuous wide-strip mill which is being lubricated by oil throughout for both the hot and cold mills. The Carnegie Steel Company at Duquesne is lubricating a 30-in. blooming-mill pinion with oil.

The Allegheny Steel Company has four stands of McIntosh-Hemphill cold-rolling mills, and the Bethlehem Steel at Sparrows Point has five mills operated on oil. One of the latter oil-lubricated mills is an 18-in. Morgan mill, the pinions of which have been oil lubricated for 10 years.

On the 14-in. skelp mill at Benwood, W. Va., the Timken roller bearings used on the edging rolls gave trouble when grease was used as a lubricant. This was remedied by piping up the roller bearings for oil. The Trumbull mill at Warren, Ohio, uses oil on the upper roller bearings and grease on the lower bearings.

Executive Committee: C. W. Lytle, *Chairman*, Geo. E. Hagemann, *Secretary*, Park T. Sowden, W. L. Conrad, Robert E. Newcomb, and W. R. Clark

As THE United States achieved the greatest yearly production of goods in 1926 and also the highest productivity per wage earner, that year has been called by some a "boom" year. On the other hand, there were none of the unfavorable symptoms such as inflated prices, so that it should more properly be considered a year of steadily increasing prosperity. This increase of prosperity began in the middle of 1924 and might have met a considerable decrease in 1927, judging from the usual length of business cycles. While 1927 has had some such indications, they have occurred temporarily and in spots, so that the year as a whole has been prosperous. In fact, commodity prices have fallen gradually, and there has been little strain on the money market. Instalment selling, while now very general, seems not to have increased excessively, and there are many who contend that as long as there is little unemployment it is a wholesome condition. Perhaps the real basis of this unusually long prosperity is the fact that wages have been very much higher relatively than prices, thus enabling wage earners to consume increasing quantities of goods. This in turn indicates that productivity has also continued to increase. Referring again to 1926, the bank savings of the United States increased a billion and a half dollars during that year, and the number of depositors increased nearly three million, so that a new high per capita saving rate of $211 was established for the country.

The Savings Bank Division of the American Bankers Association reports that more than half a million of the additional savers were depositors in school savings accounts. On the other hand, it is claimed in reliable quarters that this saving is no more than the natural compound-interest growth of earlier savings. Referring to our present $770 income per capita, and over $3000 wealth per capita, Dexter Kimball says,[1] "For the first time since the world began we are in touch with the abolition of poverty, through the tremendous output of our products." Regardless of what other factors may have contributed to the stabilization of this prosperity,[2] a large amount of credit was unquestionably due to the rank and file of American management, for competition has been increasingly keen and the margin of profit consequently declining. What is being called "the new competition" includes inter-industrial competition and inter-distributing competition as well as the old inter-commodity and international competition, for today we have silk competing with rayon, leather with artificial leather, copper with aluminum, etc., and furthermore manufacturers are taking over distributing functions, thereby competing with jobbers, and some retail stores are doing manufacturing.

### The European Situation

Our Government reports that the exports of the United States to other countries for the year ending June 30 were $4,986,000,000 against $4,283,000,000 for 1926. Imports totaled $4,253,000,000, leaving a favorable trade balance of $733,000,000. Exports of foodstuffs amount to $381,000,000 against $250,000,000 for 1926. Our store of gold increased $148,000,000. Wheat exports were two and one-half times greater than the year before.

Conditions in Europe have improved moderately, and their leaders are doing their best to gain the world markets. Foreign competition is therefore likely to affect us directly or indirectly to an ever-increasing degree. Mass production is being adopted as far as conditions will allow, and in both England and Germany there is a vast movement of regrouping and reorganizing. "Scientific Management in Great Britain,"[3] by L. Urwick, organizing secretary of Rowntree & Co. Ltd., describes the three periods in the growth of scientific management in Great Britain—the post-war period, followed by loss of interest in 1921 and a renewal of interest during the past year, the chief feature of which has been the formation of non-competitive groups interested in management research.

According to Edward A. Filene,[4] "Both the group-buying movement and mass production and distribution by large manufacturers have already advanced in Europe to a greater extent than many people realize. The chains of retail stores are progressing successfully in Germany and in England. As examples of successful modern mass manufacturing, there are the Morris car in England, the Citroën car in France, and the Batá shoe in Czechoslovakia, all of which are producing under mass organization and in mass quantities; but the trouble with Europe in large measure is that since the war it does not know how to buy its food or raw materials." Condemning the resort to tariff as a means of solving market problems, he concludes that "scientific mass production requires less and less tariff protection. The Chevrolet automobile or the Ford automobile requires no protection. Even with free trade it is inconceivable that any foreign automobiles could compete with these two in the United States markets. More than that, they could be produced very much more cheaply if the additional living cost that results from the tariff were removed, and therefore they could be exported and sold in still larger quantities than today." It is said that the name of Henry Ford is known in the remotest parts of Russia on account of the advent of the Fordson tractor.

The term "rationalization" as used in Germany is defined as: (*a*) increasing the profitableness of the industries by cutting down production cost of manufactured products to a minimum; (*b*) lowering sales prices so as to adapt them to the purchasing power of the consumers, and (*c*) making it easier for German products to compete in the world markets. They are also attempting some division of manufacturing or specialization on the part of individual plants and are establishing common sales bureaus to keep down overhead. In many ways they have gone beyond the United States in the matter of standardization.[5] On the other hand, with much less uniformity in the demands of European consumers, and with an oversupply of labor, the peculiar economic conditions of the United States are not likely to be attained.

Dr. Francesco Mauro, a leading industrialist of Italy, spent some time visiting American plants during the past year, and in summing up his impressions here, mentioned particularly the following items:

[1] "The Trend of Scientific Management," *Bulletin S.I.E.*, July, 1927.

[2] See "Stabilizing Prosperity," by Virgil Jordan, *Yale Review*, October, 1927.

[3] See *The Management Review*, October, 1927.

[4] New York *Times*, April 3, 1927.

[5] See article by E. J. Mehren in *Engineering News-Record*, August 5, 1927.

(a) High standard of living
(b) Freedom from radicalism
(c) Spirit of cooperation
(d) Amount of research.

He also paid high tribute to the influence of the late Frederick W. Taylor and Herbert Hoover. It is interesting to note the relative purchasing power of wages as reported by the National Industrial Conference Board. Taking the United States as 100 per cent, the purchasing power in Germany is 33 per cent, in Italy, 29 per cent, and in Great Britain, 57 per cent, and the average of 12 European countries is 41 per cent.

American industrialists and engineers have been welcomed as never before in Europe. As an expression of gratitude for courtesies shown the industrialists of Czechoslovakia, that government has awarded the Cross of Knight of the Order of the White Lion to five American engineers. Poland has also given the Commander's Cross of the Order of Poland to an American engineer who has served as an advisor for the past two years. In Geneva, Switzerland, there has been established an International Management Institute. Henry S. Dennison, the representative of the American Management Societies in Europe, reports that "there have been no revolutionary changes, but a considerably intensified carrying on of betterments not only in machines, but in the layout and arrangement of departments. Improvements in internal transportation facilities of every sort have been considerable during the past eighteen months." Edward Eyre Hunt, of our Department of Commerce, attended by invitation the World Economic Conference in Geneva last May and reports that "the emphasis on scientific management was very striking."[6] Forty-one countries were represented at the Fourth Congress of the International Chamber of Commerce in Stockholm last June, the U. S. having 162 accredited delegates headed by Owen D. Young. The Congress endorsed the conclusions[7] on rationalization and international industrial pools reached at Geneva by the Economic Conference. The main interest of the Congress centered on the subject of trade barriers. The retiring president, Sir Alan Anderson, called attention to the fact that there are 5,000,000 people out of work in Europe, as well as 20,000,000 others underemployed.

The third International Congress of Scientific Management was held in Rome during September and was attended by a number of American leaders. Their papers dealt with phases of "scientific organization of labor for industry, agriculture, public service, and domestic economy." In all, 176 memoranda were examined and resolutions were passed. Signor Mussolini made the closing address and asked the delegates to report that Italy was well ordered and was working out her own economic resurrection, for the progress of humanity and for peace between nations.

### Economics of Industry

It is significant that three engineers were invited this year to participate in a Conference of Economists here in the United States. Certainly the American industrialist has contributed much to the newer science of economics in the last few years. One of these new economic questions is that of thrift versus buying. Under present conditions business men are encouraging the public to buy as never before. Since current savings must be taken from current income, the value of the consumer's goods which can be currently purchased will, of course, be less by the amount of the current savings. One school of thought has therefore gone so far as seemingly to deprecate thrift. This is answered, however, by pointing out that savings may be invested in two different ways: first, in circulating capital—goods which are to go into finished goods—and second, in permanent capital to be used as a factor of production. If savings are invested in the former way, the permanent productive factors of the country are not increased. Such a use of savings does cause an oversupply of goods on the market. However, most savings get into permanent-capital goods which are not sold but used for further production and therefore constitute an ultimate demand for existing goods and are just as much a final market disposal of the existing or future market supply of goods as is the purchase of an equal amount of consumer's goods. This does not cause a future oversupply of goods. The increase in production resulting from extended permanent investment, if a stable price level is maintained, will furnish a sufficient increase in the national money income to enable investors to purchase the additional amount of goods. The equilibrium between supply and demand can therefore be maintained under conditions of an increasing production if all savings are invested in permanent-capital goods.[8]

Since primary forces are increasing the purchasing power of the masses, the maintenance of this fundamental situation is more important than to overpersuade in the matter of buying. If unemployment can be kept down and wages kept up, there will be a constancy of ever-increasing purchase power. Another writer points out[9] that business is trying so hard to get business that it is saddling itself with all sorts of expenses in trying to make people buy more goods, with the result that gross business has increased but net profit decreased. Here we have the problem of keeping down overhead. There is little question but that much can be saved in this field in the future, although an encouraging number of corporations have already brought their overhead to lower proportions. Consolidation of allied lines in order to use common resources is one of the ways of accomplishing this, but this has not always proved a sure means and overhead can be reduced in many ways without it.[10]

Ernest F. DuBrul, secretary of the National Machine Tool Builders Association, reports as the most outstanding development in that field the application of statistical methods to management. He says they are translating corporate accounts into dollars of equivalent purchasing power for different years, thereby giving executives real facts instead of the accounting delusions they have sometimes had. In this connection it is also noteworthy that statisticians are no longer content to plot nominal wages but are using curves made up to real wages, that is, the purchasing value of the wage.

Such economic problems as the best size of production lots are being studied everywhere. As many variables are involved, no practical formula has yet been developed.[11] The problem of selecting the best combination of equipment is also being studied and a formula developed some time ago has been simplified so as to permit wider use.[12]

A new danger of obsolescence has come through the continual discovery of new processes. The German process of making wood alcohol threatens present methods. Before the new process of making sugar from corn is in wide use it is announced that better sugar can be made from artichokes. The employer must be more alert than ever to avoid an enormous loss in equipment.

Hand-to-mouth buying or the use of small orders has brought about uncertainty and hardship on parts manufacturers, but

it has in the main freed capital and prevented overstocking.[13] The Packard Motor Company has reduced inventories in the ratio of 1 to 12 as compared with three years ago. The Hudson Motor Car Company is reported to turn over its material inventory every 14 days, and the Loose-Wiles Company, which handles perishable goods, every 24 hours. As a result of this, the problem of least-cost purchasing quantities is being studied.[14]

### Business Cycles

All industrialists seem to have learned the importance of leveling off the peaks and valleys of business. Forecasting conditions and coordinating sales quotas with production schedules is making progress.[15] The Policy Holders Service Bureau of the Metropolitan Life Insurance Company receives reports from 250 industrial organizations each month for analyzing and charting.

### Plants

At least forty cities are advertising industrial sites. Some of these cities are selective in their approach, some are not. The employer must consider many things before he can attempt to find the one best combination of advantages. For brief statements of these principles see T. S. Rogers' two recent papers "Should You Lease, Buy, or Build a Plant?" *Manufacturing Industries*, September, 1927; and "Factors to Be Considered in Plant Location," Mechanical Engineering, November, 1927. A particularly fine example of locating a new plant was given by O. C. Spurling in the June, 1927, issue of the last-named journal.

The past year has seen examples of illumination using as high as 20 to 30 foot-candles as compared with 10 to 12 foot-candles which was formerly considered a maximum.

### Equipment

Not only has there been a great replacement of machinery due to improvements in design, but employers have been forced to seek every type of labor-saving device in order to offset the former supply of labor from immigration. Jigs and fixtures are being used in industries that never considered them necessary. Almost every skilled and semi-skilled worker today is supplied with some kind of special machine, tool, or fixture. Material-handling equipment, rapid-drying equipment, etc. are being installed in many processes where they have never been used before.

### Labor

The record of the year ended June 30, 1927, as regards the admission of aliens into this country shows an increase over the preceding year of somewhat more than 40,000. Yet the total for this year (538,000) is small as compared with the figures for 1913, so that the figures for 1927 are smaller than those for 1920, 1921, 1923, and 1924, but larger than those for 1922, 1925, and 1926.

Last spring a conference was called by the Philadelphia Labor Union and the Philadelphia Labor Institute, also with the cooperation of Central Labor College, of Philadelphia. Morris Llewellyn Cooke presided and later expressed the opinion that the growing interest of labor in the elimination of waste was one of the most encouraging developments. If carried into effect it may bring about an altogether new era. William Green, president of the A.F. of L., pledged the cooperation of union labor in every attempt to reduce waste, but declared that the resulting benefits should show proportionately in higher wages as well as in increased profits. G. L. Gardner, author of the new book on Foremanship,[16] also reports that foremen's organizations are studying waste-elimination methods more than ever before.

With the waning of prosperity conditions, manufacturers will face the difficult problem of stabilizing employment. Perhaps there is no more important problem than this. Prof. H. Feldman, of Dartmouth,[17] says, "Protect your sales program first. Analyze your markets, simplify lines, and reduce style hazard." This is important to labor as well as to capital. Reasonably steady, regular, and continuous employment creates a better state of mind, begets a feeling of confidence, and permits workers to make orderly planning for the future. L. F. Loree[18] describes a novel measure to meet this in what he calls an "elastic" work day. It consists in varying the length of the working day between eight and ten hours in accordance with the fluctuation and volume of business. He claims it could entirely obviate the necessity of layoff.

The increase in labor productivity has been most encouraging, although figures are not up to date. The Bureau of Labor Statistics, Department of Labor, has made a study of this from 1914 to 1925,[19] and reports the following percentage increases:

| | | | |
|---|---|---|---|
| Automobiles | 172 | Leather tanning | 26 |
| Boots and shoes | 6 | Paper and pulp | 34 |
| Cane-sugar refining | 28 | Petroleum refining | 83 |
| Cement manufacture | 61 | Rubber tires | 211 |
| Flour milling | 40 | Slaughtering and meat packing | 27 |
| Iron and steel | 59 | | |

The Bureau of Labor Statistics is also conducting an investigation into the efficiency of labor in various European countries. The assistant commissioner of the bureau was in Europe last summer and made studies in Great Britain, Belgium, France, Germany, Czechoslovakia, Austria, Switzerland, and Italy.

Over 500 industrial disputes have been handled by the Conciliation Service of the Department of Labor during the fiscal year ended June 30. These disputes affected either directly or indirectly half a million workers, and it is stated by the Director of Conciliation that more than 85 per cent of the cases handled by his office have resulted in satisfactory settlements.

The Travelers Insurance Company estimates that 27,000 American workmen will receive around $50,000,000 this year in benefits from group insurance.

### Standardization and Simplification

Standardization of design has made great headway. It has reduced the amount of work in the drafting room to a minimum and is doing much to keep down stock requirements. That standardization is opposed to specialization is called a fallacy[20] by W. S. Heyward, who claims it is often possible to specialize a standardized line and to make it distinctive.

Simplification, under the leadership of Herbert Hoover and the able assistance of R. M. Hudson of the Division of Simplified Practice, Department of Commerce, has spread far and wide. There are few industrial lines which are not now working in this direction. For example, the Norwich Pharmical Company has reduced the number of items produced from 4000 to 400. During the year it has been taken up by some foreign industrialists and is considered to be one of the great contributions of American Management.

### Conservation of Material

The Department of Commerce last April reported a reduction

[20] "Sales Administration."

in the use of raw rubber amounting to 22,000 tons over the preceding year, despite the fact that motor-car registration increased nearly 10 per cent. No doubt simplification has been accelerated by the tendency to buy for immediate needs only. An interesting method of controlling rejections, that is, defective production, is described by P. F. Cooper.[21]

### Marketing

The trend is toward intensive rather than extensive marketing. With this in view some national advertising is being placed in local newspapers instead of in magazines and other expensive mediums. Part of the advertising budget is being taken for research to ascertain what the consumer really wants. Professor Freeland of M.I.T. says, "Market evaluation must be based on inclination to buy as well as on capacity to buy." The study of distribution waste has gone on with particular attention to such practices as overselling, cancellation and returns, delays on deliveries, unethical credit practices, and discrimination. The difficulty in this problem is that it lies in the twilight zone between the manufacturer, the wholesaler, and the retailer. Functionalization has therefore penetrated this field, and the term "merchandizing"[22] is being used for the function between sales and production. That is, pricing, balancing of inventories with production schedules, and analyzing of advertising mediums is being solved by unprejudiced staff men. This is sometimes carried on under a sales planning department. Some leaders are warning industry not to go much further in "mortgaging future income." The importance of establishing prestige in business is being discussed.[23]

It has been claimed that buying materials on specification instead of by trade name will save the United States annually one billion dollars. The United States Bureau of Standards alone is said in this way to have saved 100 million a year on purchases. The new simplified invoice has been formally accepted by 12 associations and over 100 important business concerns, as well as by the Federal Specification Board. It is expected that this will come into general use in a short time. During the past five years the American Railway Association has reduced the entire carriers' payments on damages from 120 million dollars to 38 million.

### Clerical Operations

Many are taking steps to reduce the cost of office work. Simplified practice, better arrangement of desks, and the segregation of typists have done much. Typists and other operators of mechanical devices when placed in a group subconsciously fall into the rhythm of the group, and a slow operator entering the group will pick up a certain amount of speed. In addition, it is important that each clerk be assigned a full day's work, which is of course the result of job standardization or time and motion study.

### Safety

The survey of the Engineering Council has been published encompassing the experience records of about fourteen thousand companies and over one-fourth of the industrial work of the country. The figures show conclusively that a decreasing productivity is usually attended with a corresponding increase in the frequency and severity of accidents, and vice versa. The report includes numerous charts and shows trends in both accidents and production of 16 basic industries. "The rate of production per man-hour for the industrial groups studied," it says, "was 14.4 per cent higher in 1925 than in 1922. The rate of accident frequency per man-hour was 10.4 per cent lower in 1925 than in 1922. The rate of accident severity per man-hour was 2.5 per cent higher in 1925 than in 1922. Many industrial executives have not given to accident prevention that degree of attention and direction which its economic and humanitarian significance warrants. There is evidence to the effect that some industrial executives feel which because of compensation insurance carried, their responsibility has been met, hence they do not concern themselves with accident prevention. The initiation of accident prevention is as much a responsibility of the major executives as is the initiation of improvements in productivity."

The United States Steel Corporation has been a pioneer and leader in accident-prevention work. Not long ago it issued a report in which it was estimated that as a result of organized safety campaigns within the company over the period from 1912 to 1923, inclusive, more than 35,000 employees were saved from serious injury. The American Car and Foundry Company, another outstanding example in this field, spent approximately $1,000,000 in fourteen years for accident prevention, but estimates that it saved $2,700,000 in actual loss by this expenditure.

There is now going on an investigation of light, sight, and safety, from which much is expected.

### Traffic Devices

The American Engineering Council has a committee at work on street signs, signals, and markings. Over sixty leading cities have submitted data, and it is hoped to include 250 cities before they finish.

### Fatigue Elimination

Dr. A. T. Poffenberger, Department of Psychology, Columbia University, has carried on experiments in his laboratory which measure the amount of oxygen and the amount of carbon dioxide involved in certain work. He has found that the efficiency of the human body as a prime mover varies much as other prime movers. For instance, there is an optimum speed for every kind of work. By his methods he is able to determine the capacity for work and the energy cost of work increments. He points out that this type of measurement must precede the study of fatigue in its relation to ordinary output, but thinks it entirely feasible to approach that relationship later on. It is proposed to eventually make studies on many types of factory work under varying conditions of monotony, noise, light, etc. As similar studies are being made at the Kaiser Wilhelm Institute in Berlin, the problem of fatigue is at last being put upon a scientific basis.

Joseph A. Piacitelli describes[24] how the Barber Asphalt Company eliminated fatigue by rearrangement of machines and by better material handling. A 20 per cent reduc ion in the unit labor cost was the result. A similar reduction of 18.2 per cent in unit labor cost is described by W. C. Hasselhorn.[25]

A. B. Segur of Chicago says: "Nerve fatigue is apparently more important in industrial operations than muscle fatigue. On fast operations very few individuals are able to maintain the same operation for more than 15 seconds without making a mismovement. In industry, fatigue forces the operator to use a longer method of performing the operation, and therefore slows down the operation."

Dr. F. Hahn and S. F. Csohar, of F. B. Gilbreth, Inc., have been studying the subject. They have compared the motion of human arms with the motion of the pendulum, and from the

[25] Ibid., August, 1927.

pendulum law point out that either to accelerate or retard the natural motion requires an extra effort, causing fatigue. They say there is superfluous fatigue if a wrong path is used or if the distribution of time along the path does not correspond with a simple harmonic motion. Undoubtedly the Gilbreth micromotion method which uses a motion-picture film is well adapted to this study, and may be expected to develop definite laws. Dr. D. A. Laird is conducting research on the noises of cities. So far it is a matter of measurement rather than of prevention, but there seem to be great possibilities in what may follow. Dr. Laird declares that noise exceeding 35 units in his scale of measurement actually increases the blood pressure of human beings exposed to it. Note also the work of Prof. H. J. Spooner of London.[26]

Vacations with pay[27] are becoming the rule and are doing much to stimulate the loyalty of employees as well as allowing them a change without financial worry.

### Incentives

The National Metal Trades Association is making an extensive study of wage incentives among their companies. Interest in incentives seems to be gaining, and L. P. Alford, editor of *Manufacturing Industries*, has observed that industries having the highest productivity also have the highest percentage of workers on some incentive plan.

Sales executives are trying incentives of all kinds, and find that by a few changes in terms the experience developed in the factory is applicable to their field. The cutting of piece rates or commission rates has become uncommon, and the response to such incentives is therefore more wholehearted than ever before.

### Research

There has never been so much importance put upon research as at present. The Western Electric Company maintains a staff of 2000 for this purpose, with an annual expenditure of more than 8 million dollars. General Electric and General Motors each spend over a million annually.[28] Concerns which cannot afford these large expenditures are either working through their trade organizations or through the facilities of universities. The American Gas Association has a comprehensive program. Systematic use of research during the last five years is believed by the Copper and Brass Research Association to have been largely responsible for doubling the consumption of copper during that period. In some cases the trade organizations have raised endowments and have used them to build and maintain laboratories on university grounds. For instance, the Tanners' Council of America and the Lithographic Technical Foundation have done this at the University of Cincinnati. The precedent of the University of Toronto retaining the patent rights from basic discoveries, is being followed in several cases. There has recently been formed a Druggists' Research Bureau, to act as a national clearing house for obtaining facts necessary to the welfare and success of the drug industry. All this is partially a result of the tendency to abandon the rigid secrecy which companies have so frequently thought necessary.

One of the most important and significant developments in this direction has been the formation of a research organization by the U. S. Steel Corporation. Here the subsidiary companies carried on a good deal of valuable though uncoordinated research and invention work for years, but the parent company kept aloof. The new body has been given a particularly high standing in the Corporation by a provision under which it is made to report to the Finance Committee, the highest governing board in the Corporation, and by having such men as Professor Millikan and Professor Johnston to direct its destinies.

### Miscellaneous Application of Management Principles

There has been some reorganization of governmental departments. For instance, the U.S. Patent Office has been studied by two engineers and a sub-committee. The report contains 108 recommendations which would considerably simplify practice.

Department stores are beginning to hire management engineers and are doing a great deal to eliminate waste. In one New York store the cash clerks have been studied by micromotion and their work standardized in the "one best way." The psychiatrist is being consulted in the matter of selecting clerks, and it is said by executives that this has proved profitable. Chain stores are succeeding by leaps and bounds, and they are doing this by the same principles used in mass production.

Agriculture is turning to research in the matter of mechanical equipment. A survey recently made includes over 400 suggestions for research. The Department of Agriculture expects to follow these up. Under the guidance of Mrs. L. M. Gilbreth, a series of lectures have been delivered at Columbia University, in which engineers have described the possible applications of management methods to the home.[29] Interest was keen. Interest was also evinced in this subject in the conferences held in Europe in the past summer. Similar reports come from prisons, hospitals, and schools at which various engineering methods are beginning to find adaptation.

### Management Societies

The New England Council, composed of eight men appointed by the governor of each state, 48 men in all, assembled about 2000 men at Springfield, Mass., in November to discuss management in manufacturing.

The American Management Association has established an Institute of Management, membership in which is elective and based on achievement in management research. The very large number of company and research sustaining members which this association has secured indicates a greater interest on the part of high executives than has ever been shown before. The Management Division, A.S.M.E., has prepared a bibliography which is more comprehensive than any heretofore published.

L. P. Alford's paper on the "Laws of Management," mentioned last year, was the first to receive the Melville Award.[30]

### Costs

Competition is forcing cost finding into all phases of manufacturing. For instance, the Utica Knitting Mills studied their factory heating and found that by revamping their old system they could save $17,000 annually. Similarly there is a renewed effort to reduce the cost of power. Hubert Collins reports four instances in which savings have been accomplished amounting to 23, 19, 13.5, and 11.8 per cent over former costs.[31]

The spread of standard cost methods has continued and is being fostered by trade associations. Manufacturers are studying labor costs as compared with carrying charges of mill equipment. The cost of obsolescence is becoming of particular interest. Budget control is almost universally in use.

### Education

Courses in industrial engineering have not increased in number as rapidly as have courses in business administration. There is, however, an increasing tendency to offer options in management to engineering students. Rutgers University, New Brunswick, N. J., has recently offered a new four-year course in industrial engineering. It is an option in the Department of Mechanical Engineering and leads to the degree of B.Sc. in M.E.

The American Council on Education is using its influence to have schools make more accurate records of conditions in all types of occupations in order to aid employers in selecting material for employment.

Trade associations are raising endowment funds for private institutions conducting courses in their particular fields. As an instance of this, the United Typothetae of America has established an endowment of $225,000 at Carnegie Institute. The Association of Cooperative Colleges held its second annual convention in Philadelphia last June and was more largely attended by employers than by educators. This is considered a very encouraging aspect. The convention proceedings may be purchased from the Secretary.[32]

### Industrial Museums

New York City has assigned to the Museums of the Peaceful Arts seven city blocks on the site of the Jerome Reservoir. This movement was started nearly 20 years ago by some of New York's public-spirited citizens: Judge Gary, Jacob Schiff, George F. Kunz, and Henry R. Towne. Calvin W. Rice was elected secretary, and Dr. Kunz, president.

At the time of Mr. Towne's death he left his residuary estate, amounting to approximately two and one-half million dollars, for this project, provided it should be successfully promoted. It would seem now with the recognition by the City of New York that the Towne bequest would become available.

Other movements, such as the National Museum of Industry, which was planned to be affiliated with the Smithsonian Institution in Washington, the Museum in Chicago, the original bequest for which, three million dollars, was given by Julius Rosenwald, supplemented by five million dollars by the city of Chicago, and the old building of fine arts occupied during the World's Fair, have been started since the original movement for the Museum of Peaceful Arts. But it is stated that they can all be made a national movement for the benefit of the whole nation as a part of the education and inspiration of all those engaged in industry.

Similar museums are proposed in Pittsburgh and in Philadelphia. The national engineering societies have indorsed both the movement for the Museum of Peaceful Arts and the National Museum of Industry, and all engineers generally should become identified with this movement as a direct contribution of the engineering profession to industry.

The Museums of the Peaceful Arts now occupy temporary headquarters at the *Scientific American* Building, 24 West 40th Street, New York, where a start has been made in organizing a great industrial technical museum for the city of New York.

### Management Week

The subject this year was Management's Part in Maintaining Prosperity. Cecil Ashdown, vice-president of Remington-Rand Company, was chairman of the National Committee, and R. M. Hudson, of the Division of Simplified Practice, was secretary. The movement has become one of national interest and has secured the support of many non-engineering organizations.

### Waste Elimination

While all of the foregoing indicates encouraging progress in the general elimination of waste, there is still a great deal which has not been done. The American Society for Thrift estimates our annual waste of coal at 750 million tons, of water at 50 million horsepower, of oil at one billion barrels, of lumber at 5 billion cubic feet. The Department of Commerce estimates that our annual waste in transportation equals one-half billion dollars, and says the shipper is largely responsible.

While materials handling has been studied more than ever, it is still thought that one billion dollars could be saved annually on payrolls by better use of present equipment and arrangement.

There were 135,000 commercial failures from 1920 to 1926-1927, inclusive, with total liabilities of $3,500,000,000. Seventy per cent of all the failures in 1924–25 and 25–26, occurred in the trading groups, and their share of the total liabilities increased from $37^1/_4$ per cent in 1924 to 49 per cent in 1926. Bradstreet's analysis of causes of failures during the years 1922 to 1926, inclusive, gives "incompetence" as the reason for 35 per cent of the cases, and "lack of capital" for 33 per cent more. The other 27 per cent are scattered among "inexperience," "extravagance," "speculation," "fraud," etc.

Finally, although most of the bankers and leading financial men are far from pessimistic, they are advising their correspondents and clients to get their affairs in better liquid condition for the spring of 1928. As far as the engineer is concerned, his influence has definitely increased and his doings are becoming desirable news for publication. The owner of business is now less apt to confuse the mechanisms of management with the spirit of management, and thus the reaction against so-called "efficiency" is vanishing.

# Production-Control Methods in the Rubber Industry

## A Statement of the System Employed in the Akron Plants of the Goodyear Tire & Rubber Co.

By F. B. CALHOUN,[1] AKRON, OHIO

A FEW years ago the rubber industry was expanding very rapidly. This was due primarily to artificial stimulation in industry caused by the conditions existing shortly before and during the World War. As a result, the most important economic matter of all, "the production of maximum output with present equipment and facilities at a minimum cost," perhaps was not given sufficient consideration. Subsequent developments were inaccurate records, excessive raw-material inventories, poor turnover of in-process materials, excessive material wastes, and an exceedingly high rate of labor turnover.

It should be borne in mind that the rubber industry is seasonal, subject to violent fluctuations in the price of raw materials and sales demands. The conditions above cited led the Goodyear Tire & Rubber Company to organize methods to meet this situation in the most satisfactory manner possible.

The first step was to segregate the various functions essential to production control. These included the ordering and control of productive materials, the issuance of schedules, the dispatching of materials through the different processes, the stocking of raw and finished materials, transportation, and shipping.

It should be understood that these functions were actually in effect, but so decentralized or distributed between the various departments, that the management had no instrument which would permit efficient control. The selection and training of proper personnel, qualified to handle this work, presented quite a problem in itself, due to the fact that personnel experienced in control work was not available.

### Materials Control

The function of the production-control division at the present time begins with the ordering of materials required to produce the various products manufactured. A yearly estimate is developed by the sales department, outlining probable requirements on each product manufactured by the company. This program is carefully analyzed by the management. When approved, it provides the basis for additional capacities and plant facilities where necessary. If any changes in design or equipment are contemplated the yearly estimate is given to the consulting engineer, who formulates commitments, and in turn works out the program.

This estimate is revised monthly to meet changing conditions in sales demands. This revised estimate is broken down into its component parts by the production-control division. Occasionally sales increases on certain products may largely exceed previous plans and require greater floor space, more equipment, more men, and more materials. Likewise, a decrease in sales may mean that curtailment must be made. Consequently, a definite tentative manufacturing schedule, broken down into specific quantities on each item, is compiled from market reports. It is then delivered to the production-control division. These estimates are submitted thirty days in advance of going into effect. They cover periods varying from thirty days to six months, depending upon the product. The factory decides whether the tentative program is possible.

### Ordering Materials

This schedule forms the basis for releases and for planning the requisitions of materials which are not ordered on a contract basis, and on which quick shipments can be secured. The production-control division regulates the inventory on all productive materials.

From the tentative production schedule, a purchasing budget of materials is prepared. This is sent to the assistant comptroller. When approved it goes to the purchasing department as an authorization to fill the requisitions which will be placed by the production control division. The purchase budget shows the quantities of materials on hand, en route, and on order, and the coming month's requirements. In addition, the definite needs for two months ahead and the probable needs for four to six months ahead are listed. The probable inventory is also calculated for four to six months in advance. These data form the basis for contracts for materials which can be most advantageously purchased on commitments and released on shipping orders.

Purchase requisitions are made out after these budgets have been approved. The backs of the requisitions are ruled for purchasing records. In our attempt to synchronize incoming materials with consumption we are, in some cases, scheduling the plants of our vendors. To facilitate this plan further we are gradually revising layouts so that incoming materials may be dispatched direct from the receiving platform and stocked adjacent to the point of consumption. This program has enabled us to reduce storeroom space and handling charges.

### Production Schedules

Daily, weekly, bi-weekly or monthly, depending upon the product, manufacturing tickets are made up within the limits of previous estimates, and forwarded through managerial channels to the production-control division. These tickets are first checked to see that all material and equipment are available for producing. This procedure is very important in the control of in-process material because if a definitely prearranged schedule is interrupted at any point of process, due to a shortage of material or equipment, surplus inventories will result.

All products are classified as follows: First, standard stock. Under this classification are all products that are sold in sufficient quantity to justify stocking both at Akron and in the branches. Second, Akron stock. Under this classification are all products that are sold in sufficient quantity to justify a stock at Akron only. Third, special manufacture. Under this classification are products that are made to order only, such as customer's brands, conveyor belting, hand-built hose, etc.

When the requirements are received by the central control division, they are broken down into daily machine schedules. In the compilation of these schedules, the following points are considered; First, economical grouping in order to obtain maximum machine capacities and minimum waste of material. Second, relative importance of orders on hand. An emergency order system has been found necessary because of the policy of low

[1] Manager, Production-Control Division, Goodyear Tire & Rubber Co., Akron, Ohio.

Presented at the National Meeting, Rochester, N. Y., Oct. 26–27, 1927, of the Management Division of The American Society of Mechanical Engineers.

inventories in all lines of industry. With the flexibility which has been created in labor and equipment, emergency orders are handled without confusion.

### Labor Control

Labor requirements are studied in a thorough manner to facilitate carrying out the production program in the most effective manner. The labor department is called upon when the ticket is received to supply trained men in numbers sufficient to handle the production. As such men are not always immediately available, the labor training department must have time to engage and train them when a larger force is to be put on, before the ticket becomes effective. Likewise, when reductions are made, the labor department must be informed so that it will stop engaging men to be trained. In such cases, transfers of employees to other departments that are active can be made, and hardships to workers avoided.

The control organization confers with the production and labor training foremen relative to the type of work and the number needed. Requisitions for labor and daily labor conditions reports are made out by production control for the various production departments.

### Importance of Thinking in Production Cycles

The personnel working on basic schedules must be trained and developed to think in terms of production cycles. If the central control men do not do this, one department will not be properly synchronized with another.

All products, either standard or special, when placed on schedule, are allotted a definite time for completion. Occasionally normal production time limits must be extended due to a sudden influx of emergency and special orders. When this occasion arises, the merchandise distribution department is promptly notified in order that the sales department may be informed that it is necessary for the branch or customer to wait longer than usual on the particular product affected.

In order correctly to synchronize the flow of material through the plant, it is necessary for all machines to work to a time standard, scientifically determined. Therefore, all work is scheduled by machine minutes. The chart used in breaking down orders into minutes is based on piecework rates.

### Workers' Interests Guarded

In order to eliminate discontent on the part of the pieceworker, earnings over an 8-hour period must be considered at the time the schedules are written. Each schedule or order received from the merchandise distribution department is broken down into production minutes and a chart is posted at intervals during the day showing work ahead of each group of machines. By the use of this chart, a decision is reached as to the number of machines and working shifts required.

### Dispatching of Work

A mathematical breakdown of incoming orders is not difficult, but a daily schedule properly coordinating equipment, labor, and material, and synchronizing one department with another is a task of unusual difficulty. It has heretofore been found necessary to station at different control points throughout the plant, a dispatching organization to provide shift schedules based on local conditions and assign work in accordance with the predetermined schedule. The dispatching organization must keep the schedule men, located in central control, informed in regard to back schedule, breakdowns, inexperienced labor, and various other kinds of essential information.

The centralized control of all schedules and the assignment of work to machines throughout the plant is the only method by which production can be regulated to assure harmony and uniform operating conditions.

In the tire departments where certain machines are assigned indefinitely to a specific construction, the dispatching function is mainly one of keeping process inventories properly in balance. However, in the case of certain mechanical-goods departments, where a job may represent only a few minutes' work to a machine, the task of keeping the machines properly supplied with work, without delays, is rather difficult.

To assist in this work, the dispatcher is provided with job assignment orders, serially numbered, outlining the specification of the particular product. Dispatch boards have been installed and these orders are so arranged that the condition of the department is semi-graphically outlined. By this method, the production-control organization dispatches material through all operations in production and into the finished stock and shipping departments. The job assignment order is the authority to manufacture all products and its design varies with departments.

These assignments are typewritten and represent the largest amount of product that can be economically routed through the different departments without producing congestion, but still keeping all machines busy and providing an orderly sequence of work. The assembly of the assignment order is composed of as many copies and colors as are required for assignment of work to each individual operation, for maintaining the records necessary to intelligent dispatching, and for the rendering of the operator's or crew's time.

In the control of the wrapped-hose department, which is representative of other mechanical-goods departments, the assignment order consists of six copies; first—special white (for cost department), second—white (for stock cutting operation), third—blue (for tubing operation), fourth—yellow (for building operation), fifth—salmon (for finishing operations), sixth—pink (for finishing and assembling operations).

Each copy is sent to the succeeding operation after the previous operation has been performed and serves as authority to produce the quantity specified. Completing the operation, the supervisor places on the face of the copy, the name of the operator who did the work, the quantity, and the time required. This form is next returned to the control station. Here the clerk inserts the piecework rates and extends them to show the labor cost. This sheet, which takes the place of the traditional time card, goes to the accounting department.

### Cost Data and Time-Keeping

The labor costs are summarized from the detailed sheets, transcribed to a master sheet, and then identified by factory order, specification, and operation numbers. As the labor is charged directly against each operation and product, this system enables the accounting department to determine just what each product is costing. In this way the products which are failing to produce a profit may be gradually eliminated and efforts concentrated on lines which make a more satisfactory return. The payroll is likewise made up from these sheets.

The combining of timekeeping and production records has reduced possibilities for errors and has eliminated much duplication in clerical work. The rendering of time and the supplying of basic cost data is a dispatching function. Generally, the making out of all time is now being handled by the production-control department.

After the different copies of the assignment order have served their purpose in dispatching material through the production departments, three copies of this order accompany the material to the stock room. One copy is receipted and returned to the production-control department where it is filed with the manufacturing order for reference on deliveries, in case any question

arises after the material is shipped. Another copy goes to finished product control which in turn notifies the merchandise distribution department that the product is available for shipment. The latter department then releases the shipping copies of the order. The third copy, in some cases only, is retained by the stock room for use in identifying material.

### Daily Reports

Daily production reports are made by each plant, summarized from the records of all shifts in each department. These reports cover the work scheduled for each line of product, the amount turned out, the overrun or shortage, the losses and their causes, the number of workers in each department, number of absentees and a summary of the total schedule, the actual production and the amount over or under the schedule. Daily condition reports are also turned in by the supervisors stating the causes of any difficulty experienced.

A monthly report summarizes these factors in all departments of each plant. Items requiring attention are pointed out and desirable changes in equipment and methods are suggested.

### Organization

TABLE 1 SUMMARY OF CLASSIFICATION OF PRODUCTION-CONTROL PERSONNEL

| Classification | Number employed Plant No. 1 | Plant No. 2 |
|---|---|---|
| 1 Manager | 1 | 1 |
| 2 Foremen | 3 | 3 |
| 3 Head supervisors | 6 | 6 |
| 4 Central control | 7 | 5 |
| 5 Chief dispatchers | 15 | 14 |
| 6 Senior dispatchers | 50 | 41 |
| 7 Junior dispatchers | 58 | 39 |
| 8 Stock dispatchers | 12 | 13 |
| 9 Scalemen | 7 | 14 |
| 10 Secretarial, clerical, and checkers | 48 | 33 |
| 11 Clerical and messenger | 1 | 2 |
| Present department average | 200 | 156 |
| Total in plant | 217 | 171 |
| Total in Plant No. 1 | | 217 |
| Total in Plant No. 2 | | 171 |
| Assistant superintendent and manager | | 2 |
| Total | | 390 |

TABLE 2 CLASSIFICATION OF DUTIES OF PRODUCTION-CONTROL PERSONNEL—PLANTS NOS. 1 AND 2

| | |
|---|---|
| Manager | In charge of plant functions and personnel. |
| Foremen | In charge of division. |
| Head supervisors | In charge of control functions and personnel, several departments. |
| Plant Nos. 1 and 2—Central Control | Contact, master schedules, and materials control. |
| Chief dispatcher | In charge of station—all shifts. |
| Senior dispatcher | In charge of shift—local schedules and dispatching. |
| Junior dispatcher | Floor dispatching and timekeeping. |
| Stockkeeper | Handling and dispatching stock in and out of storage points. |
| Scalemen | Weighers. |
| Secretary and clerical | Typists, clerical work, and checkers. |
| Clerical and messenger | Clerical work and messenger service. |

### Wage Incentive Plan

Our experience on incentive plans of wage payment is somewhat limited. The establishment of piecework rates or incentive plans of wage payment has not fallen within the scope of production-control work at the Goodyear Tire & Rubber Co. It is economically correct that the operator of exceptional merit shall receive an exceptional day's pay, the average man an average day's pay, and the poor man a poor day's pay. The piecework method of wage payment recognizes this fundamental principle. The management of the Goodyear Tire & Rubber Co. has not thought it advisable as yet, other than in an experimental way, to install any incentive plans of wage payment.

However, the mechanism necessary to operate any plan of wage payment successfully is now established. Correct information for control, costing, and wage payment has been provided. The possibility and temptation of cheating by operators has been eliminated. The management tells the operator what he has produced and renders all time, rather than the reverse practice. Before wage incentives were considered in an experimental way it was believed that delays and hindrances attributed to managerial causes must be reduced to a minimum, in fairness to the operator. We believe this condition has been created in a satisfactory manner. The possibility of increasing plant efficiency through incentive stimulants becomes correspondingly less where scientific schedules and proper standards for execution are set and enforced by the management.

These remarks are made with the understanding that a well-developed plan of scientific management must include incentive plans of wage payment and as previously stated, the Goodyear management is now working experimentally on this problem based on quantity and quality.

One of our most important operations is final inspection. A form of incentive plan was introduced to see whether or not it would have any effect on quality. The basis of the incentive plan was an allowance of 50 per cent for quality of a certain standard, and 50 per cent for quantity. This system was in operation but a short time when it proved conclusively that the quality of the product had depreciated. Immediately the basis of the payment was changed to 90 per cent for quality and 10 per cent for quantity. The quality of inspection on this operation is at a higher point today than it ever has been. This particular plan has rested upon its merits and has proved successful.

### Summary

To summarize briefly, an analysis and classification of the steps required in manufacturing has been made. Departments have been fully organized to handle each type of work that is to be done. A close relationship has been developed between these departments so that they work together. Output is based upon market demand through direct contact between sales and production departments.

A logical, and as far as possible, automatic procedure has been established to put orders in shape for rapid manufacturing and to have men, equipment, and materials ready to handle production on a definite, smooth schedule. Production control, or the responsibility for the scheduling of work and the coordination of men, equipment, and materials to do it, has been definitely separated from actual production, or the doing of the work. Local units keep in constant touch with the progress of work and see that schedules are lived up to every hour of the twenty-four Inventories and work-in-process have been radically reduced.

Finished stocks are kept at an economical level, but distributing branches are amply served and shipping dates are met.

Employment has been stabilized. Labor has increased in efficiency. Developments are still producing equally remarkable results, and the management has demonstrated beyond a doubt that production control in continuous process industries can be made a complete success.

## Discussion

W. S. Richardson.[2] Before one can really enter into a discussion of any particular application of scientific management in an industry, consideration must be given to the peculiarities encountered within that industry. The practices incidental to the application of the management plan can then be examined and the method of surmounting the obstacles be observed.

[2] Manager Planning Department, B. F. Goodrich Rubber Co., Akron, O.

In the first place, production control reduced to its least common factor, undoubtedly is that function in organization whose aim is to produce a given quantity of product in a given time with a given quantity of raw material. In order to be able to accomplish this in the rubber industry, particularly on products known as mechanical rubber goods, wherein the demand rises and falls in rapid cycles in an industry which requires a high degree of technical skill and a great variety of raw material, the following obstacles will be encountered:

1 Shortage or excess of raw material required in producing a given quantity of product in a given time
2 Rapid variation in the demand for trained labor to meet and balance the rapid changes in the production rate, particularly on mechanical rubber goods
3 Variation in the production rate due to defective material prior to and subsequent to process
4 Variation in the production rate, due to equipment breakdown
5 Variation in the output per man.

Let us examine the first obstacle, material supply, and see how, in the instance presented, the matter is handled. The production-control department has a knowledge of the articles and quantities to be manufactured thirty days to six months ahead of the actual production period. This information is forecasted by the sales department and insofar as mechanical rubber goods are concerned, is the only instance within the industry that such a set-up has been effected. It is the backbone of effectiveness for production control, and from any angle is a highly commendable practice, reflecting a very well organized plan of merchandise distribution which carries the product direct to the consumer.

With this knowledge a breakdown into material requirement is comparatively simple. But to supplement this we find that the production control department has responsibility for plant raw-material inventory. This means that while it must see that the purchasing department procures sufficient raw material at the required time, it must also see that it does not procure too much. This is accomplished by means of purchase releases issued by the production-control department to the purchasing department, indicating the quantity and the time at which any material is to be brought into the plant. This is a novel idea as applied to the rubber industry.

The second obstacle is the supply of labor involved in an industry with rapid changes in the production requirements. Here the production control has a real weapon in the shape of a supply of super-labor which can be used at its discretion to maintain the required labor in uniform balance to meet a predetermined rate of production, and also to absorb the shock incidental to rapid increases or decreases in the output required by sales. This is an extremely happy plan. It merits full consideration in the avoidance of costly labor turnover in a large plant manufacturing a diversified product, which has widespread use and requires rapid delivery after the actual placing of an order.

The third obstacle is always present in the rubber industry; namely, variation in production rate due to defective raw material or defective product. Here it appears that the production-control department at the Goodyear plants has made no mention of any facts which would tend to show that this had been overcome. The industry would certainly welcome any foolproof safeguard against this contingency.

Nor do we find any solution for overcoming the liability of equipment breakdown, although the flexible labor supply would in most instances permit average breakdown loss to be rapidly discounted.

Variation in the output per man, will, in the absence of a wage-incentive plan, generally be found to rest at a fairly uniform level. To discount any variation, the Goodyear production control has two weapons—first, the flexible supply of trained labor; second, the data it can accumulate incidental to its rendering of output per man to the timekeeping and cost departments which permit it to put into process only such quantities as the records indicate can be accomplished; third, its network of dispatchers who can quickly reflect any condition in either direction that may tend to build up the in-process inventory.

In summary, it can be said that from all angles, the fundamentals underlying the plan of production control as established at the Goodyear Tire & Rubber Co. have much to commend them in any continuous process industry. From the point of view of a company in a similar line of product, facing the same problems, one cannot do less than to state that much of value can be gained from giving serious consideration to the adoption of methods as fitting to the needs of the times as those practiced at Goodyear.

The writer's company has been working in this same direction for the past two years. While the work has not progressed to the degree current at Goodyear, more territory is being embraced. Side by side with production control, wage payment incentive plans are being developed, and in addition, a plan to govern the consumption of raw material within the limits of the amounts used in costs, much the same as labor is governed. This function which has been separated from the direct production forces is called material control. It embraces control of all the elements of waste, both seen and unseen, occurring along the production route. It is needed in the rubber industry in the control of plant and in-process inventory as much as is control of the rate of output, for an excess use of any material beyond the understood limits will do much to make unsteady and ineffective other controls that have been set up.

The Author. Problems peculiar to the rubber industry, which are mentioned in Mr. Richardson's discussion of my paper, will no doubt continue so long as present conditions and processes of rubber manufacturing exist. The solution is largely one of organizing methods to meet these various irregularities in the most effective and economical manner possible.

Methods which are now used at Goodyear in overcoming these obstacles seem to be understood with the exception of the manner in which we handle machine breakdowns, defective materials, variations in labor, etc.

In addition to disruption of previous estimates and plans caused by changed conditions in the sales field, provisions have also been made to safeguard against excessive waste and local plant irregularities. These irregularities are caused mainly by replacement of defective material, changes in specifications, machine breakdowns, damaged auxiliary equipment (such as molds, cores, etc.), experimental and emergency orders, slow and fast labor, absentees, over or under running of schedules, and other items too numerous to mention. The efficient accomplishment of plans to cope successfully with these disturbing factors, which oftentimes cannot be foreseen or planned in advance, must be immediately regulated by adjustments of schedules and labor.

A suitable mechanism of control, sufficiently flexible to meet these constant changes, has been provided to assist in insuring proper turnovers and desired deliveries of finished product. This function and responsibility is handled by a local combination scheduling and dispatching organization which reassigns work in the proper sequence to suit the needs and means available at each operation in the particular circle involved.

In connection with the controls which have been set up at Goodyear to smooth out variables and irregularities, the management is also constantly applying corrective measures and improvements which tend to reduce disruptions and the resultant waste to a minimum.

# Coordinating Wage Incentives and Production Control

## A Short Account of the Various Methods That Have Been Tried in the East Pittsburgh Works of the Westinghouse Electric & Manufacturing Company, Together with a Description of the Plan Finally Adopted and Now in Use

By D. B. CHARTERS,[1] EAST PITTSBURGH, PA.

THE forty-two years that the Westinghouse Electric & Manufacturing Company has been in existence have afforded that company considerable time in which to try most of the plans advocated for increasing production by means of wage incentives, and it is the purpose of this paper to explain briefly the plan which is now in use as a result of this experience and to tell how it can be applied to other than productive labor in order to obtain the condition suggested by the subject of this paper.

The plan developed is known as the Standard-Time System of Wage Payment and has become the adopted plan in our work.

The fundamentals of the Standard-Time System are a day rate, a standard-time rate, and a time allowance.

The day rate is considered as being a fair rate for a certain class of work in a community when paid for on a day-work basis.

The standard-time rate is a certain percentage higher than the day rate, and is offered as an incentive to perform the work within the time allowance. When speaking of a "class" of work, reference is to the Westinghouse plan of job classification wherein all jobs in the shop are placed in one of five classifications, namely, unskilled, repetition-routine, semi-skilled, skilled, and highly skilled.

A range of rates, both day-work and standard-time, is assigned to each class of work and is recorded on what is known as the "key sheet." This sheet shows the maximum and minimum rates that may be paid for all classes of work, and is used by the Employment Department when hiring help.

The standard time or time allowance for a given operation is the time which can be met by an average worker working normally under average conditions, and is obtained by means of a time study.

A time study is a study of the detail operations required to complete a certain job, and the recording of the time in such a manner that comparisons and selections may be made. A study should only be taken when conditions are satisfactory and the methods standard as to motions and their sequence.

Whenever possible a formula is compiled from the time-study data, and for any given operation will cover all conditions likely to be encountered. Consistency is one of the most important advantages of the formula, or perhaps it could be better stated were we to say that the formula tends to eliminate inconsistencies.

### Principles of the Standard-Time System

A standard-time allowance is established on each operation or job. When the time taken to perform the work is equal to or less than the time allowed, the operator is *paid for the time allowed* at his standard-time rate, which is, as already stated, a certain percentage higher than his hourly day rate. When the time taken is *greater* than the time allowed, the worker is *paid for the time taken* at his day rate. From this procedure it is seen that the worker is guaranteed his hourly day rate.

A decided advantage in connection with the application of the Standard-Time System is that it affords a means for checking the efficiency of each worker. This is accomplished by means of what we call a "fall down" card and a performance chart. The advantages to be gained by the system depend largely upon the proper handling of the "fall downs." By "fall downs" are meant those cases where the worker does not complete the work within the time allowed.

The procedure that has been adopted as standard for handling "fall downs" is as follows: When time slips are turned over to the time clerk, he promptly extends the time, and in all cases where the worker has failed to meet standard time, he makes out a "fall down" card and forwards it to the time-study man who interviews the worker in order to determine the reason for the fall down, correcting all cases where the failure was due to causes over which the Time-Study Department has control. After making the proper notations, the "fall down" card is sent to the foreman, and after receiving his comments and signature, it is sent to the performance-chart clerk, where a graphic record of the worker's performance is made. The card is then sent to the time-study foreman, who, after approving, sends it to the general foreman. The general foreman makes his observations and returns the card to the Time-Study Department to be filed. By this method each of the interested parties are made familiar with the details of the trouble and are generally enabled thereafter to avoid a repetition of the same difficulty.

The performance-chart record furnishes valuable information to the foreman and superintendent when re-rating and selecting men for promotion. It also provides a ready means of checking the progress and development of new workers. The efficiency of an entire section or department may readily be determined and comparisons made between different departments throughout the works.

In comparing the standard-time system of wage payment with other well-known systems, one of the points that might be criticized is that the time spent in preparation for placing a standard-time allowance on a job is sometimes considerably more than required by other systems. This extra time, however, is necessary because all conditions must be normal, all superfluous motions eliminated, the mechanical features approved, and the design of the apparatus or part checked so as to be sure that the worker is working to the best advantage. The time allowance set under these conditions is quite likely to remain stable, the workman is able to figure his income with a considerable degree of accuracy, and the company is reasonably sure that the cost of the article is right. On the other hand, if a value is placed on the job without these precautions, many revisions will probably be necessary as the search for improvements goes on under the urge of increased earnings. It is even quite probable that a workman will hesitate to advance his ideas if he knows that improved methods will lead to reduced values. The unit of value, or "time allowance," is expressed in decimal hours, which is easily understood and is not subject to misinterpretation, while some other systems use special names for their units of

measurement, which, after all, are nothing but periods of time. The allowances for fatigue and personal needs are based on observations extending over many years and made on thousands of different jobs. They are easily understood by the workman, who has confidence in the justice of the allowances, based as they are on actual performances. It would seem that this procedure is to be preferred over the secret and mysterious allowances used in some other systems. In a plant such as the Westinghouse at East Pittsburgh where many of the workmen have had twenty years of experience with various and sundry wage-payment plans, they are almost as well informed as some of the experts, and any plan which cannot be readily explained and understood would fare badly. It will be noticed that in this plan of incentive wage payment there is no provision for compensating the foreman and other non-productive workers for any extra effort put forth. From the years of experience with various wage-payment plans it has seemed best to keep entirely separate any plans for compensating the productive and non-productive workers. That is to say, the productive worker should not provide directly through his own efforts the reward for extra effort given to the non-productive workers. It is granted that the interest in increased production should be a common one, but even the appearance of rewarding one group at the expense of the other should be avoided. Some systems provide that should the worker earn more than his regular hourly rate a portion of the extra earnings shall be given the non-productive workers for their efforts which have enabled the productive worker to produce and earn more than would otherwise be the case. The productive workman eventually becomes possessed of the idea that some of his earnings are being used to compensate the non-productive workmen.

Some other advantages of the Standard-Time System are that it is applicable to both standard and special lines of work. Again, the payroll work is simple, being only the hours allowed for the work multiplied by the standard-time rate. Further, the rate differential is so proportioned that while the incentive to speed exists, the lower rate is high enough to accomplish easily the change from incentive work to day work.

Although the results obtained from incentive systems have been remarkable, there are at the same time some disadvantages which occur from having a number of workers concentrating only on their own individual production. Each worker realizes that he is paid only for what he produces, and it is but natural that he should strive to increase his own output, regardless of everything else. He feels that he has no time to help out new men or give a fellow-worker a hand when he is in difficulties, and he is unwilling to lose time hunting lost material, or doing a little extra work for which he is not directly paid but which will improve quality, speed up work as a whole, or help out the supervisory force. Lack of cooperation between the men and the management and among the men themselves is often evident. In order to correct such conditions, the Westinghouse Company has devised a group system. That it has accomplished its purpose has been proved by successful application in many and varied lines within the company. It is not to be doubted, however, that its application in industry as a whole has been decidedly limited. It will be well, therefore, to set forth the fundamental principles upon which the group system is based, together with a discussion of its advantages and disadvantages, so that those who have not heretofore done so may see where the group system may be introduced to advantage in their own industry.

Assume that two workers of about the same degree of skill and working with the same effort work side by side on the same class of work. They notice that, although they work in about the same manner, they do not produce equal amounts of work each day. One will produce more than the other, depending upon the conditions met with. One may run out of material or may be delayed by tool breakage, or may experience any of the thousand-and-one delays which occur occasionally. The other man, in the meantime, is having a better run of luck, and he is able to produce more on that particular day. These two men, wishing to steady their daily earnings and to secure the fullest cooperation from each other, mutually agree to pool the work done by each, and at the end of each day make an equal division of the total. These operators, then, have formed a group. This same agreement may be made among three, four, or any reasonable number of men. When a group is formed by the men themselves, however, the number of members of the group is generally kept small; for the arrangement usually calls for an equal division of earnings, and only men who are capable of producing nearly equal amounts of work are willing to band together.

Groups formed by the men themselves occur in industry, but they are not common. Generally workers on the same class of work possess different abilities, and the greater producer is not willing to enter into an agreement with the lesser producer. Rather, groups are organized by the management, and a payment system devised whereby each man shares in the earnings of the group *in proportion to the amount of time* he works in the group and *in proportion to his ability*.

A group, then, is a number of workers working on the same class of product who pool the product of their labor, and the method of distributing the earnings of the group among the workers is known as the Group System of Wage Payment.

### Advantages of the Group System

*Better Cooperation.* There is greater cooperation among men in a group than among individuals. Since everything that will aid in the completion of the work will mean more money for the group and hence for each man, the individual is willing to help his fellow-workers whenever necessary. For instance, if a man needs help in lifting a heavy casting on to his work bench, he will get that help under the individual incentive system only when his neighbor has finished what he is doing and when it suits his convenience to give a hand. Help is often given grudgingly, and at times there is wrangling between the men, particularly if they do not happen to like each other for personal reasons. In a group, one man will set personal feelings aside and help another man willingly, because by so doing he knows that he is helping to increase his own earnings. This willingness to cooperate with one another increases with the length of time the group works together, until a group spirit is built up which will affect every man in the group.

Lost time caused by waiting for a moveman to bring more material, waiting for the tool room to grind tools, and other small delays which would cause the individual operator to lose time, is practically eliminated under the Group System. If the operator is forced to stop his own work for any reason, he will help another man in the group on another operation, or he will do some odd job which will aid the group as a whole.

Again, one man of a group will be more careful in performing an operation if he knows it will aid the next man in performing the following operation. For example, one man milling a casting which is then to be drilled will try harder to remove all burrs so that the piece will fit smoothly into the drill jig used by the next operator in the group. If any burrs must be filed off he will do this while his machine is making the next cut. Thus the drill-press operator can work steadily with no lost time. Such things, although small in themselves, amount to considerable time in the aggregate and will increase the overall group efficiency and consequent earnings to quite an appreciable extent.

There are always some jobs which are not as desirable from

the worker's viewpoint as others. The work may be heavier or more complicated than the average; it may be more disagreeable, or it may be a short order which will not allow the worker to get into the swing of the work and thus work more efficiently and make higher earnings. No matter what the cause, if the job is undesirable, under the individual system, there is a tendency for the operator to shun it in the hope that eventually some other worker will do it. This makes it more difficult for the planning department to get such jobs through the shop, and often these orders are seriously delayed. A group, on the other hand, realizes that it will eventually do the job and that there is no particular advantage in setting it aside and favoring other work. Thus the schedule clerk has merely to inform the group leader when the job is wanted to be reasonably sure of getting it. This materially lessens the work of the planning department, and tends to reduce the number of overdue orders.

*Reduction of Supervision.* Many workers object to so much being spent for overhead, for they feel that they are supporting the so-called non-productive employees. This feeling is minimized under the Group System, for the amount of supervision and hence the size of the non-productive supervisory force is greatly reduced. The group leader is, in effect, made an assistant foreman. He is, however, in much closer contact with the men under him than the assistant foreman would be for he generally has fewer men to handle, and he works side by side with his men. The group leader is personally interested in what his men produce, for their production affects his earnings, while, as a rule, assistant foremen are paid on a fixed salary basis independent of production.

The group leader gives instructions to his men and sees that they work properly. He makes certain that they are using the most efficient methods and that they interpret drawings and shop information properly. The foreman merely instructs the group leader in a general way, leaving to him the working out of the minor details.

The size of the planning department is reduced by the Group System. Instead of assigning jobs to each individual man, it tells the group leader what jobs are wanted next and leaves it to the group leader to get the jobs done. Obviously, it is easier for the planning department to deal with ten group leaders, each of whom supervises nine men, than it would be to deal with the hundred men as individuals.

Under the Group System, few instructors are needed. The group leader and the other men in the group all help to show the new man how to go about his work more efficiently. The new man tends to learn from members of the group in a shorter period than he would under an instructor since they are in more constant contact with him. The older men realize that the sooner they break in the new man, the sooner they will get the full advantage of his efforts. The new man is anxious to show the group that he is capable of working with them, so he strives more earnestly to learn than he would under an instructor.

*Reduces Non-Productive Labor.* Under the Group System it is often possible to include in the group material handlers and other service men so that they may share in the efforts and earnings of the group. For instance, suppose that one man is needed to bring materials to and remove finished work from a group of ten men. By increasing all time allowances applicable to the group by some percentage, it becomes possible to include the moveman in the group, and since his earnings are affected by the group he will be more willing to help them than when he was working as an individual and had no interest in greater production. The group leader will be quick to find simple jobs for him to do when he has no material-handling work to occupy him. In time this man will be able to learn to do the harder jobs, and eventually he may be able to take his place in the group as a full-fledged artisan, and, of course, will share in the earnings of the group to a greater extent. The service men as a whole will realize that they have a chance to improve themselves and get ahead, and it will be possible to get a better class of men to accept and keep such jobs. Labor turnover will be reduced, and at the same time new skilled workers are constantly being developed.

*Simplifies Costing and Time Keeping.* Where actual costs are determined on every job that goes through the shop, a very large cost staff is required under the individual system. Under that system each man that works on a job turns in an individual time slip on that job. When the job is completed, all the time slips are assembled. The amount paid each worker on each time slip is found by multiplying the time earned or the number of pieces made, as the case may be, by each individual rate. The total of those amounts gives the actual labor cost of the job. If the job comes through the shop later and is worked on by different men at different rates, the actual cost will be different. If a breakdown occurs while the job is being made and the worker neglects to turn in an extra time slip covering the delay, the job will be charged with the time lost, while in reality it does not deserve this charge.

Under the Group System the cost is computed from the average wage rate of the group multiplied by the total time allowance for the job. This makes a very simple method of costing. Unless the personnel of the group changes or unless there is an increase or reduction of wage rates in the group, the cost of making the job will be the same every time it goes through the shop. Minor breakdowns are not charged against any one job but are distributed over all jobs.

Time keeping is made much easier under the Group System. Each man turns in only one time slip a day. On it are his name, check number, group number, and the amount of time worked. The amount earned is figured either from the shipping report of the section or the shipping report of the group as made out by the inspector. Thus the time keeper has only as many time slips to handle each day as there are men in the group.

### Bonus Plans Adopted

As mentioned before, the problem of coordinating wage incentives and production control has been handled by the Westinghouse Company in a somewhat different manner than is usual in most systems, and some of the ideas that have served their purpose or now exist will be discussed.

During the World War when the need for production was so great that cost was a secondary consideration, the workmen were offered such incentives that unprecedented effort was given and the wages were enormous. At such a time it was useless to expect the foremen, clerks, and other non-productive workers to exert themselves proportionately for their regular salary which was perhaps one-fifth to one-half what a hard-working lathe hand could count upon earning. This was taken care of by the following bonus plans.

*Supervisory Bonus.* This plan provided for payment of bonus to the supervisory force identified primarily with production. It affected salaried employees observing shop hours and superintendents and assistant superintendents who did not observe shop hours. It did not include inspectors, time-study men, or time, cost, and estimating clerks.

Bonus was based on four factors:

1 Production
2 Percentage of Overdue Orders
3 Expense Control, and
4 Man Efficiency.

A load or "bogey" for each factor was set for each section on production as follows:

*Production*—Load fixed for each month by Central Production Department

*Percentage of Overdue Orders*—Bogey fixed for each month by the Central Production Department

*Expense Control*—Bogey based on past records and not changed from month to month

*Man Efficiency*—Bonus paid one-half the average percentage increase of the workmen's earnings over standard.

Five (5) per cent bonus was paid on each factor where load or bogey was met. Three (3) per cent bonus was paid where 95 per cent efficiency was reached. The bonus earned on all factors were added and the total represented the percentage added to the salary of each participant.

If efficiency fell below 95 per cent on any factor, no bonus was paid on that factor. If efficiency fell to 85 per cent on any one factor, bonus on all factors was canceled.

If the load was exceeded or if results were better than represented by the bogey, 1 per cent additional bonus was paid for each 5 per cent increase.

*Time, Payroll, and Checker's Bonus.* An allowance of $3.50 per month was made for handling the time and checking of each workman. An average was taken on the number of accounts closed in by the Payroll Department for the two pays of the month, and should this average, for example, be 1000 accounts, the total allowance for earnings of time and payroll clerks and checkers for that month would be $3500. Should the actual salaries of this group amount to only $2500, one-half the amount saved, or $500, would be paid the group as bonus, subject to the following deductions based on the equality of the service rendered:

1 Before prorating that portion of the bonus payable to the payroll and time clerks a deduction will be made of 50 cents for each pay shortage.

2 A 2 per cent bonus deduction will be made from time clerks and checkers for each 1 per cent error in the checkers' counts as revealed by the inventories. This deduction will be based on the average error of all operations.

On certain kinds of so-called non-productive work the output is not directly proportional to the effort expended, for example, material handling, receiving, storing, and issuing of raw materials and the like. Investigation on this kind of work has shown that with an increased effort of approximately 10 per cent on the part of the worker it is possible to increase his output about 100 per cent. As an example of this condition take the case in which a man goes to a storeroom presenting a requisition for one piece of a certain item. To supply this piece the storeroom attendant receives the requisition, refers to his records to locate the proper bin, goes to the bin, picks up a piece, and delivers it to the man at the window, recording the withdrawal in the ledger.

Had this requisition specified two pieces instead of one, the work involved on the part of the storeroom attendant would have been very slightly increased, yet the output would have been doubled. In order, therefore, to place work of this nature on an incentive basis, it is necessary that this condition be taken into account. The following formula was accordingly designed to be used in such cases:

$$(\text{Established Time} - \text{Time Taken}) \times F + \text{Time Taken} = \text{Time Allowed}$$

where $F$ is a factor representing the increase in effort necessary to bring about an increase of 100 per cent in the output. In most cases this factor is equal to approximately 0.10. An example will illustrate the method of figuring earnings from the formula. In a storeroom there is a group of nine men. In a certain pay period there were 96 working hours, or the "Time Taken" was equivalent to 96 × 9 or 864 man-hours. Material for 700 control-panel sections was delivered to the floor by the storeroom group at an allowed time of 1.50 man-hours per panel. The "Established Time" would therefore be equivalent to 700 × 1.50 or 1050 man-hours. Using a factor $F$ equal to 0.10 and substituting in the formula, we have,

$$(1050 - 864)\,0.10 + 864 = 18.6 + 864 = 882.6 \text{ man-hours allowed.}$$

This example shows the results obtained from a wage-payment system which is founded on the theory that the worker should be paid for the time taken plus some fraction of the time he saves; that fraction, which in the example was $^1/_{10}$, depends upon the amount of increase of effort required to give the increased output. In other words, if the worker does twice as much work to turn out twice as much product, he should be paid on a straight standard-time basis, or his incentive factor would be 1.0. If, however, as already explained, it is only necessary to increase his effort $^1/_{10}$ to double his output, this factor should be 0.10.

This method of figuring allowed time on work of a non-productive nature is used quite extensively at East Pittsburgh and appears to be looked upon favorably by the workmen, while it is quite interesting from the company's standpoint to know that excessive earnings, or earnings out of proportion to the effort expended, will not be possible.

Production, time, and cost clerks may increase their earnings by additional effort through a standard-time plan based on time necessary to get an order properly recorded, checked and into work. It might be well to state, however, that although this plan has been carefully considered and has all the earmarks of a practical plan, it is not yet in use.

The route through which an order travels in each section should be laid out in order to eliminate back-tracking and lost time.

Each stock order will be classified according to the number of different steps or operations through which it must pass. For example, an order calling for a certain type of apparatus, may require issuing a considerable number of requisitions, ordering parts from different feeder sections, drawing material from storerooms and requesting material through the Purchasing Department. Assuming that this order requires as much or more labor than any other, we shall call it Class A, for which will be established a time value in man-hours for performing the work. All orders requiring the same number of operations or within a reasonable amount to be listed in the same class. If the range becomes too great other classes may be established such as B, C, D, and E, for which separate time values will be set.

The time elapsing between the receipt and completion of the order will afford sufficient time in which to study and classify each order. The performance record will not be taken until the jobs are shipped.

All clerical help in a section that assists in recording, ordering material, issuing time cards, writing labor cards, shipping, or compiling costs in connection with an order, will constitute one group. The production clerk in charge in the section will be recognized as the group leader. It will be his duty to plan and supervise the work.

At the end of each semi-monthly pay period a record will be made of the number and classes of jobs shipped. The total number of jobs in each class will then be multiplied by the established time value which will give the total time allowed for each class. A total of the time allowed for the different classes will then be made which will equal total time allowed.

From the semi-monthly time reports will be taken the time actually worked by each member of the group, a total of which will equal the time taken. These time reports must be approved by the head of the division or some one to whom this duty has been delegated.

In order to calculate the earnings of the group, proceed as follows: $\frac{\text{Time Taken}}{\text{Time Allowed}}$ = Performance percentage. Opposite this figure in the table below will be shown the percentage to be added to the earnings of each individual in the group.

The flat wages of each member of the group will be increased by this figure except in such cases where an individual has been absent or late, when it will apply only to that portion of his earnings covering the time actually worked.

Overtime will be counted as time taken, but no compensation will be allowed in addition to that earned by the incentive plan.

When the percentage figures less than 10 per cent the group will be considered as having failed to qualify and will be paid their flat earnings.

| | Percentage to be added to earnings of each individual of group |
|---|---|
| Time taken more than time allowed | 0 |
| Time taken equal to time allowed | 10.1 |
| Time taken 90 per cent of time allowed | 11.1 |
| Time taken 80 per cent of time allowed | 12.5 |
| Time taken 75 per cent of time allowed | 13.3 |
| Time taken 60 per cent of time allowed | 16.7 |
| Time taken 50 per cent of time allowed | 20.0 |
| Time taken 40 per cent of time allowed | 25.0 |
| Time taken 30 per cent of time allowed | 33.3 |
| Time taken 20 per cent of time allowed | 50.0 |
| Time taken 10 per cent of time allowed | 100.0 |

It will be noticed that all persons up to the foreman in charge can be placed on an incentive plan. Some may feel that the foreman should be included, but experience has shown that it is well to have some person in charge of the group who will have no direct financial interest in the result and can therefore see to it that undesirable means are not used for obtaining temporary advantages.

It may be asked whether or not the incentives offered the workmen in the wage and bonus systems herein described, have any off-setting effect in increasing accidents along with increased production?

In view of the dismal accident record of industries generally, until comparatively recently, the question is a perfectly proper one.

It is beginning to be recognized that a really efficient shop is at the same time a safe one—that is, one phase of a business cannot be developed at the expense of another and in our own shops experience has borne this out.

Careful study has been made of every disabling accident over a period of several years and not a single instance has yet been found where an accident even remotely could be traced to excessive speed as a result of a wage incentive. Safety is never sacrificed to speed, but on the contrary there have been occasions where the reverse has been true, and the fact that our accidents have decreased 81 per cent in the past five years, is offered in confirmation of this statement.

Summing up in a few words, it would seem that coordination of wage incentives and production control can best be obtained by furnishing a common interest in greater output through entirely separate wage-incentive plans and compensation for the different groups involved.

## Discussion

G. D. Bearce.[2] The author clearly outlines the production control and bonus system used by the Westinghouse Electric & Manufacturing Company at East Pittsburgh. Further development of the standard-time system of wage payment is the most logical of any of the bonus systems that are in vogue. It assures the worker of a fair rate of pay and provides him with an incentive to increase his productivity.

The procedure termed the "fall down" method of keeping track of the ability of the worker should be very effective. The term, however, is quite harsh, and from the standpoint of psychology, the workman should not be accused of falling down, but rather have it brought to his attention that an "unfulfilled task" is charged against his record.

One of the first questions considered, when the bonus system is undertaken by a plant that has never had experience with wage incentives, is the cost of operation. The author might present information of this nature which would enhance the value of his paper.

In the discussion regarding the value of paying bonuses to non-productive labor, the fact should not be overlooked that doubtless considerable of this type of labor is necessary to operate any bonus system. Consequently if bonuses are not paid to non-productive labor, at least the added cost of operation for a bonus system should be deducted from any savings that such a system might make possible.

J. E. Dykstra.[3] While the writer personally believes that the standard-time system is as easily applicable to any plant as any of the various incentive systems, and more so than many, yet it would seem that the system outlined by the author would present problems in some lines of endeavor that would make its application, as a whole, a matter of some difficulty. Not every factory is so situated as to make a group system possible, and this is especially true of some of the so-called job shops, where quantities are always limited and size and quality of the work are greatly diversified.

The special benefits of the group plan are given under the heads of Better Cooperation, Reduction of Supervision, Reduction of Non-Productive Labor, and Simplifying of Costing and Time-Keeping. These four items enumerated are readily operative and applicable in all cases where production and the product itself permit the grouping of a number of individuals of similar skill, and where the production operations are somewhat similar. Assembling operations will most readily fall under this classification. We should, however, be mindful of the fact that there are many factories having departments employing from 10 to 30 people, and yet have in these departments such diversified equipment that everything from a crankshaft for a 300-hp. engine down to a special capscrew for a 10-hp. engine, or a clutch must be produced. Under such conditions, the writer believes that the four items just mentioned as a natural sequence of the group system become extremely difficult of realization, and that even the group plan itself becomes difficult of application.

The fourth item, Simplifying Costing and Time-Keeping, which could possibly be applied to the units produced as a whole, becomes at once an impossibility, when an accurate parts cost is necessary in order to determine a reasonable price for replacement parts. It naturally becomes impossible for one man to make out one time slip for a day's work when he may work on as many as a dozen or more jobs during the work day.

The second and third items, Reduction of Supervision and Reduction of Non-Productive Labor, also lose much of their possibilities under such conditions as those mentioned; and the first item, Better Cooperation, becomes largely a question of management and leadership.

Nevertheless, the outstanding items described by the author are perfectly applicable in all classes of manufacture. The most important items as the writer sees them are: The classification

[2] International Paper Co., New York, N. Y. Mem A.S.M.E.

[3] Factory Manager, The Champion Chemical Co. & The Foos Engine Co., Springfield, Ohio. Mem. A.S.M.E.

of equipment and manufactured parts; and a systematic time study, fully analyzing each operation and its tooling possibilities, plus a reminder system or "fall-down card," when any one employee fails to perform any operation within the time limit set.

It is surprising what faulty conditions can be brought to light when we once go through our various departments in the manner covered in the paper. No one would deny the benefits that can be obtained from an incentive system of wage payment, and usually some bonus scheme can be evolved to cover both productive and non-productive workers.

The writer has been able to obtain gratifying results under manufacturing conditions, similar to those described by the author by the creation of a contingent fund, consisting of a percentage of the premium earned by the productive workers during the month. This contingent fund provides for penalties in case of over runs on standards set, as well as work spoiled in the process of manufacture. It is at the end of the month divided on a predetermined basis, between department heads, non-productive and productive workers in the department.

It is fortunate for the engineering profession that no given system can be applied to all of our diversified manufacturing systems, but by judicious application and some modification, almost any of the recognized incentive systems can be profitably employed and can be introduced without any appreciable friction from the workers. It is needless to say that the simplest possible system that will bring results is the most easily introduced, and that no system should be introduced before a thorough study of its possibilities has been made under given factory conditions. The introduction of a system, when once determined upon, can best be accomplished by a competent member of the organization, perhaps under outside supervision of an expert, if necessary. Most schemes that are working satisfactorily are usually the products of a continuous growth and application, and quite frequently systems are working that bear only a fundamental resemblance to the scheme originally installed.

M. C. Rosenblatt.[4] Of the plan outlined by the author no criticism can be offered. This is to be expected, since the plan is backed up by many years of experience for these particular shops, and is the fruit of evolutionary processes where the good in previous plans has been retained and the bad discarded. The plan itself is accurate, commendable, and workable and should be increasingly successful if the principle behind it is fundamental. Whereas the details of the plan respond completely to logical analysis, it is a matter entirely of opinion as to whether the principle behind it is correct and will withstand the ever-changing labor conscience.

A wage incentive with the proper production control is made in order to increase the rate of production with the same facilities. It operates to create a greater profit for the invested interests. It does not, in itself, better the welfare of the operative any more than if the operative diverted his time when out of the shop to his own monetary profit, since he is giving more to production and quickly realizes this. If, by means of the wage incentive, overhead is decreased and, therefore, net profits increased and the wage incentive and a share of the extra earnings on the invested capital are linked together, then the best results will obtain.

Wage incentives in themselves have a tendency to produce inferior work, unless the operative or group is instilled with the thought that such work cuts down the net profit and indirectly reacts against him or the group and all of the workers where they are also interested in the net earnings of the business. If there is a tendency to produce inferior materials, greater supervision and inspection become immediately necessary, with the attendant negating of the monetary gain expected.

The rate at which work is turned out is a function of the operative's own natural ability and disposition, the facilities at his disposal and, primarily, his mental and physical health. The operative sets his own pace for any particular task to which he is put. The wage incentive merely adds an artificial stimulus and does not correct any of the fundamental factors of rate. This added stimulus must take its toll somewhere, which may be either in inferior work, greater mental and physical fatigue with the attendant greater turnover, or in other fashions.

The formality of bonus pay for the fast worker over a long period of time becomes commonplace and expected. He becomes accustomed to the higher rate and overlooks the fact that he earns more because he produces more. He finds in time a need for the higher pay and conveys this idea to his associates who may, in themselves, belong to the group of slow or awkward workers. The reaction does not set in until there is a change of employment when a higher rate seems to be demanded and a new plan evolved.

While the writer has no criticism to make of the plan so completely analysed by the author, he is not entirely satisfied that such plans, *per se*, are the complete solution. Capital produces the only unearned increment. The producer-consumer wage earner pays himself.

W. M. Passano.[5] The writer has had some experience with a system of wage incentive, similar to the one described by the author, but in the printing industry. In principle, our system of standard times and wage incentive is the same as that in operation at Westinghouse, and has been in successful use for the past six years. The fact that printing is virtually a craftsman's industry, and in this way differs somewhat from a strictly manufacturing industry, may account for the fact that certain modifications of the methods described by the author have proved desirable in our business.

The main point in which our experience has not agreed with the Westinghouse Company's experience is that we have found the group system not desirable, although in certain departments we have had to use it as a matter of necessity. It has shown itself unsatisfactory, from our standpoint, for the following reasons: First, the workers resent having a poor producer in the group. It has been said that when such is the case, the management should keep its hands off and the good producers will make it so hot for the poor producer that he will either have to get out or do better. Quite often, although it is impossible for him to do better, other good reasons exist for keeping him in the group. He may be a versatile man who can be moved from one department to another as conditions demand, or he may be a very old and loyal employee. From the management's standpoint, these reasons will be sufficient to continue employing the poor producer, although the workers cannot see it this way.

Second, we have found that the workers in a group go even to the point of resenting the management's hiring inexperienced help. They point out that hiring experienced help, by paying higher wages, would make it unnecessary for them to spend time in teaching the inexperienced.

Third, the chief disadvantage we have found with the group system is that by not keeping a record of the individual's production, we lose a desirable control of the situation. We use the individual's production record as a basis for increases in pay and laying off in dull seasons. This would have to be left to the foreman's judgment if the record of the group were all that were known.

[4] Specialist in Acoustics, Philadelphia, Pa. Assoc-Mem. A.S.M.E.

[5] Waverly Press, Inc., Baltimore, Md. Jun. A.S.M.E.

On the other hand we have felt keenly all the disadvantages of the individual incentive system which the author describes; but it has been our aim to attempt to devise ways of eliminating these weak points. The undesirable features of the individual incentive methods and the ways in which we have attempted to correct them may be listed as follows:

1 When a productive worker is delayed for any reason, such as helping a fellow-worker, teaching a fellow-worker, lack of material, or anything beyond his control, he is permitted to note on the back of his time ticket the number of minutes that he has been delayed. Then this amount is deducted from the time taken to perform the operation.

2 We too have experienced the condition of slighted work due to the men's anxiety to make high records. Our system is to return all unsatisfactory work to the man who originally did it, and let him make it good without receiving any credit for the time so spent. Where this is not practical, a record is kept of the cost of correcting the poorly done work, and this cost is deducted from his bonus.

3 Of course, it is impossible to have all jobs equally difficult or equally desirable, and if the men are left to their own resources, they will, naturally, fight shy of the short-takes and mean jobs. We have established the system of having the foreman distribute the work among the men in an impartial way, so that each man gets a part of the fat and lean.

4 The author mentioned the advantage of a working foreman with a small group. We have found it equally advantageous to have a working foreman in charge of a group of men who are *individually* rewarded for their production.

5 We have established a method of obtaining standard unit costs with a minimum of clerical work, despite the fact that each man receives an incentive in proportion to this *individual* productivity. As our scheme may be interesting a brief description of it follows.

Each man works on only one time ticket per day. On this ticket he lists the operations on which he works and the number of units that he produces. By detailed time study, we have determined a standard time for performing each of these operations, and the clerk at the end of the day computes the standard time allowed for the work which he has done. The actual time, of course, is taken from the time ticket. The standard time divided by the actual time is the man's efficiency. Similar records are kept for every one in the department, the average of which gives the efficiency of the department.

To determine the unit cost of any operation, it is necessary simply to take the standard time for the operation, divide it by the efficiency of the department and multiply the quotient by the *hour rate* of the department.

It is interesting to note that we do not attempt to keep separate time records on individual jobs or operations, but that we obtain standard unit costs, which are bound to be correct on the average.

Although many have felt that it is impracticable to attempt to standardize a craftsman's industry, we have found that rewarding the workers, in proportion to their production, has proved most profitable in the printing business.

J. F. Mattern.[6] Many shops of much smaller size than the one described by the author are endeavoring to discover some means of setting time allowances whereby a man is assured of a little better rate of earning, provided he uses extra effort and gets out more work in a given time. There are just as many different means of arriving at this end as there are shops working on the problem. There are, no doubt, many shops in which time-allowance systems have been tried and subsequently have been thrown out. If we were able to get definite data on the various reasons for failure of time allowance systems, we should very likely come back to the fundamental basis of all of these systems, and that is the method of setting the rate in an equitable manner and the stabilization of the rates in just as equitable a manner.

The author states that standard time allowance is established on each operation or job. He describes the motions for checking the efficiency of each worker by means of the "fall-down card." He subsequently handles the fall-down card clear through the organization until it gets back to the time-study file. The amount of work involved in handling this card would make a big impression on the small shop executives, in view of the number of persons involved. The amount of clerical work involved, the time of supervisory checking and comments, the final recording on the performance card all take time and money. This brings us to a question.

Are any data available which will show the approximate cost in time and money, to set a standard time allowance for an operation, handle the time cards, make out a fall-down card, interview and check the worker for his side of the story, get the foreman's comments, check up all the performance charts, check on the time-study foreman, refer to the general foreman, and then to the time-study department for comment and file?

Another question along the same line, which ties up with the first question, is: What percentage, in the light of experience, of the total number of standard time allowances handled, would be estimated for "fall down?"

These two questions are fundamental, and they are of vital importance to a shop executive who is looking for a means to increase his output per man and still trying to keep this man well paid and consequently happy. Not many organizations are as large as Westinghouse, and very few industries could support the overhead charges of such a system, particularly if the shop is engaged in irregular work of a jobbing nature. If the author can give us a general answer on these two questions, many of the executives in smaller shops will get an entirely different view of the possibilities or impossibilities of using similar systems in their own shops.

J. G. Wegman.[7] The plan proposed by the author is entirely consistent in most respects. On one point, however, the writer has a divergent point of view.

It is apparent that the author does not approve of permitting foremen to have any direct financial interest in the effort earnings of the productive operators. However, he grants that the interest in increased production should be a common one. So many influences affect productive effort and earnings that to divorce the productive operators' and foremen's incentives or rewards for extra efforts would at once separate many other interests that must be common.

Inherent higher productive operators' earnings, where there is mutual or common incentive, leaves absolutely no doubt or question in the productive operators' minds as to mutual integrity toward the common goal of each. Reciprocity becomes a factor in every phase of departmental operating.

The incentive plan, when mutual, wherein it is possible for the productive operators' efforts and earnings to peak and the foreman's earnings to show no increase is rapidly bringing out increased attention to each and every phase affecting the productive operator.

To bear out this statement consider the foreman, assistants, and group leaders who find it to their direct monetary benefit to manage in their own spheres with the following factors to consider and improve: operators' earnings, costs, source of supply, quantity and quality of supply, job rates and operators'

[6] General Superintendent, Elliott Company, Jeannette, Pa. Mem. A.S.M.E.

[7] North East Electric Co., Rochester, N. Y.

rates, day work, waste, overtime, idle time, production schedules, time studies, methods and method changes, clerical work, trucking, and janitor labor; each of these directly affecting the foreman's earnings. Is it not plain that productive operators will get more intelligent service under a system of this nature? And is not this service insured when a foreman's earnings are proportionate to the degree in which the service is rendered?

In making the incentive common to productive operators and foremen we simply bond together all interests that should be common. And here mutual cooperation becomes conspicuous because of the reward affecting every person.

When productive efforts prove above normal and the individual productive or non-productive operator is paid in direct proportion on the same basis, the productive operator is quick to grasp and appreciate that he and the so-called non-productive operator or foreman and his assistants are incentively bound to a common goal. He sees non-productive labor at his service more than ever, all because of this service reward. And, further, his constructive demands become more numerous. For example, as foremen, we may often allow some weakness in conveyors or other devices to be temporarily neglected. Now, if foremen and men are bound together by a common incentive plan, the men will not hesitate to call such matters to the foreman's attention. They not only know that they have an absolute right to do so, but they know that it is to the mutual interest of the foreman and themselves that they do so.

Under other plans need the foreman be so aggressively interested in the operator when the reward of each is not common and interdependent? He should be, but is he?

Base service rewards on anything you will—they inherently show where all interests must be vitally common and each dependent on the other, and impelled by an incentive that is a common one towards the common goal of livelihood. Therefore, how can it be possible to place in separate incentive spheres the productive operator and his foreman?

Surely we would not be influenced sufficiently to divorce interests that should be common, by the remote possibility of the use of undesirable means to gain temporary advantages by a foreman or his productive operators. Unfortunate incidents of this nature are, as a rule, traceable to morale that has been warped by neglect of common sense or economic unbalancing from any cause. Has industry grown to its present size by the use of undesirable means to gain temporary advantages? Or has it grown by just the same impulse that started it—confidence in someone else?

With our nation's largest and most successful industries striving constantly to have their employees assume direct financial interest by any number of attractive plans to the extent of $450,000,000 in employee-stock ownership, the writer cannot believe that anything is jeopardized where foremen and operators are bound in common interest by a common incentive.

Ray Flagg.[8] In the first part of the paper the author states that if a worker performs a task in the allowed time or less, he is paid for the time allowed at his standard-time rate, which is a certain percentage higher than his "hourly day" rate. This would indicate that when a worker does a job in less than the allowed time he gains in two ways. He is not only paid for more time than he really puts in on the job but he is also paid for this time at an advanced rate. This would mean that mistakes in setting standard times would be doubly disastrous, and since some mistakes are sure to occur it would be interesting to know how much trouble this causes.

In order for a wage-incentive system to function to its best advantage, the worker must be given a guarantee that the standard time will not be cut for some definite period after it has been put in operation in the shop. If this policy is pursued in the case of the author's system, the setting of the so-called "allowed times" would have to be done with a degree of care that would make them exceedingly costly as well as slow to work out. From the description given of the methods used to determine "allowed-times," it appears that the executives of the Westinghouse Company appreciate this weakness in this system and have employed such measures as are at hand to minimize its effect. In this connection, the author should tell us on what this percentage increase of the "standard-time rate" over the worker's "hourly day rate" is based, and about what this percentage amounts to in dollars and cents. He also should tell us if the Westinghouse Company guarantees that it will not cut a standard time for any given period after it has been put in use?

Under the heading of reduced supervision the author points out that by applying this incentive system to a group of workers rather than to individuals, the amount of supervision necessary is lessened. The writer doubts this, for it has been his experience in handling groups that it is very difficult to get satisfactory group leaders. If it were possible to get group leaders who are willing to spend the extra time and effort that is required to manage a group, without any additional compensation other than a share in the additional earnings of the entire group, the author might be right. Again, a group of men is not curbed by conscience as is an individual. A group of men will do things to other groups and to their employer that the individuals composing the group would never think of doing as individuals. In the light of these facts it would seem that really what happens in this case is not a lessening of the amount of supervision necessary, but rather a shifting of it to other shoulders. Could the author tell us just what trouble, if any, the company has had in procuring satisfactory group leaders?

Under the heading "Simplifies Costing and Time Keeping," the author states that under the group system the cost is computed from the average wage rate of the group multiplied by the total time allowed for the job. This probably would average correctly over long periods of time, but on comparatively short jobs or jobs on which a part of the men in the group worked, it would unquestionably lead to very serious error. Also in the case of "fall downs" and the like, this average could not hold. Is this system used generally on all jobs where this wage incentive is used, or only on jobs where the entire group works on the job and the task is completed in the allowed time?

There is no doubt but that this system does aid in the costing and time keeping as long as the entire group is employed on a single job, but is likely to lead to complications under any other set of conditions. With these facts in mind, it would seem that this system is only usable in old established concerns where the output is thoroughly standardized and large enough in volume to employ groups of workers in place of individuals. This system likely works well in the Westinghouse organization, and for its needs it probably would be hard to improve it. The scheme used to induce the workers on the non-productive payroll to render better service accomplishes its purpose very creditably, but it too could not be expected to function under different conditions.

To judge a system of this character, without a knowledge of the executives back of it, and of the factory conditions under which it works, is apt to be misleading. An inferior system well managed will often give satisfactory results while an excellent system poorly handled may fail miserably.

MAN-50-4

# Production Control in a Wrought-Brass Mill

By W. R. Clark[1] and Arthur Brewer,[2] Bridgeport, Conn.

*This paper describes the scheduling system which has been worked out satisfactorily during the past two or three years in a brass mill. The object of this system is to give better service to customers, to reduce inventories, and to stabilize employment. The paper contains flow sheets of the operations involved and is illustrated by charts and tables showing the variations of flow of material and the mechanism of control. The detailed procedures are outlined. The system accomplishes the following results: it enables careful prediction of the rate of production and means for planning it to meet current business; it enables prompt notification to the customers of the expected date of shipment and insures the fulfilment of this promise; in keeping productive facilities elastic, it permits the control of semi-finished and finished stocks, the control and reduction of inventories, and an accurate determination of mill hours and number of employees, the whole stabilizing the production rate and ironing out the fluctuation in cost due to variation in the volume of orders.*

This discussion will be confined to that section of the Bridgeport Brass Company known as the Mill Products Division, which has to do with the manufacture of brass and copper sheet, rod, wire, and tube.

These products are sold to the trade or delivered to the Fabricating Division of the company. The latter is the largest single customer of the Mill Products Division and for purposes of this paper will be considered as any other large customer. The sequence of manufacture is generally as follows:

## Flow of Materials

Copper, zinc, and brass scrap are the principal raw materials used. (See Fig. 1.[3]) With the exception of certain copper shapes purchased outside, these materials are weighed out in the mixture department to produce the various mixtures and are then placed in metal boxes, each containing approximately 220 lb. These boxes are check weighed and delivered to the casting shop by conveyor where they are placed on the charging floor by overhead traveling crane. In the casting shop the materials are melted in induction electric furnaces and the contents poured into molds of various shapes. These molds produce tube shells, round billets, and flat bars in various sizes and lengths up to 6 ft. long. Tubes are produced either by cold drawing direct from tube shells or by first hot piercing round billets and then cold drawing. The number of cold draws necessary runs from a minimum of two to a maximum of twelve. Annealing, pickling, pointing, and sawing operations are required between draws. Rod and wire are produced by first hot extruding round billets, hot rolling round billets or cold rolling flat bars, and then cold drawing to the finish size. From one to seven cold draws are necessary with annealing, pickling, and pointing between draws. Sheet is produced by cold rolling flat bars or first hot rolling flat bars and then cold rolling to finish gage. From three to nine cold rollings are necessary with annealing and pickling between rollings.

The finished products are made in a large variety of mixtures, sizes, and degrees of hardness or softness. Because of this great variety it is impossible to stock a great amount of finished material, except in the standard rod sizes used in screw machines and the standard brass-pipe sizes used in the building trades. Semi-finished stocks are maintained at various points, however, to facilitate quick delivery of finished product.

The major problem consists of maintaining a rapid and even flow through the mills of the materials required. It requires the maintenance of an active semi-finished stock at certain points

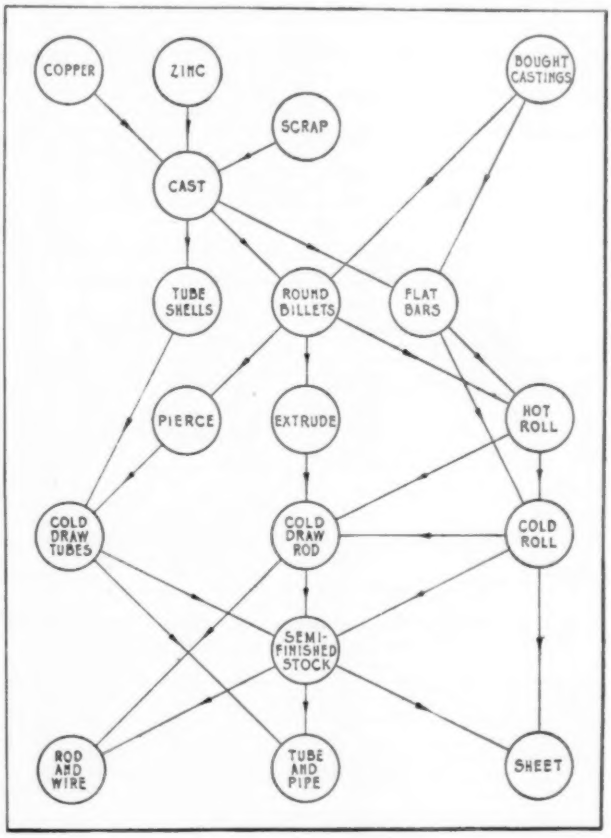

Fig. 1 Flow Chart

in the manufacture from which various sizes and tempers can be finished. It necessitates the grouping of small orders calling for similar sizes and materials into larger lots for more efficient manufacture. Production and shipment of each order must be accomplished at the time specified.

Normal capacities for a normal working week of 50 hours have been worked out for the various groups of equipment. Variations in the working week and the number of employees are predetermined, based upon the condition of the order balance and the sales department's estimates of forthcoming business.

## Order Balance

When an order is received by the sales department it is given a place in the production schedule and the customer is notified when the order will be shipped. As this acknowledgment must be made promptly, it should be made by the sales department. The shipping date must be accurately set, so that the mill can

Fig. 7 Weekly Order and Production Report

accurately fulfil the promise made. To insure this the sales department must be governed by definite limitations.

About the middle of each month representatives of the mill and the sales department meet to set a production schedule for the following month. Just prior to the first of the month they again meet to discuss modifications in the schedule, if necessary.

In order that the rate of production shall be properly set, curves are kept showing the order balances (see Fig. 2). These order balances consist of (*a*) blanket orders, namely, orders—size and date of delivery to be specified later—covering a customer's 30- or 60-day requirements, so that he may take advantage of the metal market, or coverage on his contracts; (*b*) inactive orders, namely, those specified for delivery within a period greater than 30 days; and (*c*) active orders, namely, those required within 30 days. These curves show the metal obligations and regulate the purchase of raw materials.

### Orders Received

Curves are kept showing the current receipt of orders and their relation to the production schedule (see Fig. 3). As the rate of receipt of orders varies greatly, week by week, a four-week moving average also is plotted in order to smooth out these violent fluctuations. These curves, with information received from the salesmen in the field, after due rationalization,

form the basis of estimates of the probable incoming business in the immediate future. They also give a very clear picture of past experience.

### Finished Stock

Curves are kept showing the condition of finished stocks and their relation to shipments and production. (See Fig. 4.) Where possible, the production of stock is used to compensate for the variation in production of active orders, thereby stabilizing mill operation.

### Inventories

Curves are kept showing the condition of the inventories. (See Fig. 5.) These curves are cumulative: (*a*) mill process inventory plus (*b*) castings on hand plus (*c*) semi-finished stocks plus (*d*) finished stocks plus (*e*) raw material. Maximum and minimum allowable inventories are set monthly by formula, depending on the production schedule. These curves with the production schedules form a basis for the setting of the requirements for raw materials.

### Production Schedule

The product of each mill is divided into groups, such as condenser tubes, heater tubes, pipe, and miscellaneous—the latter being divided into five sub-groups, depending on size and gage. A production schedule is then made up for each group based on the order balance, anticipated new orders, and desired change in finished stocks. The combination of the groups gives the total mill schedule. (See Fig. 6.) The production schedule combined with changes in semi-finished stocks and process inventory gives the net metal requirement. This metal requirement combined with the expected scrap to be made in process gives the gross mill requirement. The normal mill hours for the month divided into the production schedule gives the production schedule per normal mill hour, indicating the labor-hour requirement for the month.

A summary of all the mills gives the total anticipated new orders, changes in finished stocks, production schedule, etc. The net metal requirement combined with the desired change in the metal-room inventory gives the total net metal requirement. The gross mill requirement is divided into outside purchases and castings to be made in the casting shop. The weigh-out then is indicated to produce these castings. The total net metal requirement is broken down to show the amount of each raw material required to produce the adopted schedule.

From this detail of the net raw-material requirement the purchasing agent can accurately purchase or specify delivery on contracts in accordance with the exact amount of each raw material required. Thus, by insuring that we have only the necessary raw materials on hand and controlling the process and stock inventories, the total inventory may be kept to a minimum, thereby producing the maximum metal turnover.

### Order and Production Report

Should the rate of incoming orders change suddenly, these production schedules can be immediately revised. A weekly order and production report is made, showing the relation between the monthly sales budget, anticipated new orders, and actual rate of receipt of orders. (See Fig. 7.) These figures give an immediate indication of a desirable change in schedule. The orders received to date and the production to date are accumulative for the month. A comparison of the monthly production rate and the monthly production schedule gives an indication of how well the mill is living up to the schedule adopted.

### The Monthly Schedule

The monthly schedule is divided into periods of a week's duration. A Kardex Rand Chaindex pocket is made out for each group and period. As each order is received it is transcribed on to a production-order form and a Chaindex Card is made out in triplicate and placed in the correct pocket for the period in which shipment is to be made. (See Fig. 8.) Identical Chaindex files are kept in the sales department, the production office, and the mill superintendents' offices.

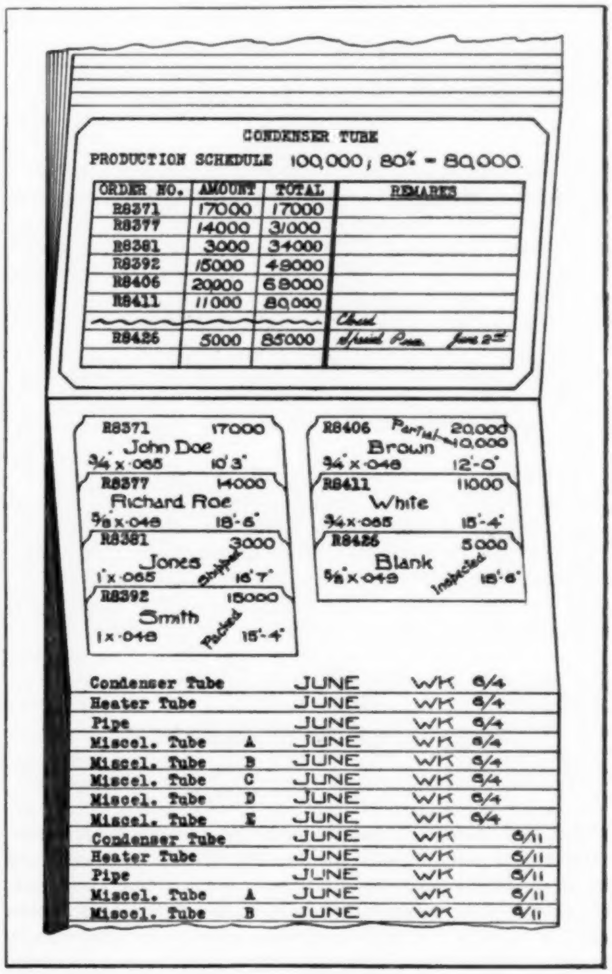

Fig. 8 Chaindex Schedule Records

Some groups require more time than others to produce after the receipt of order. Therefore, schedules are closed one, two, three, or four weeks, as the case may be, before the shipping date. Schedules are also closed when the total amount allocated to any group and period reaches 80 per cent of the production schedule. This 20 per cent reserved capacity is kept open for such hurry orders as may afterward be received and to allow flexibility in mill operations.

A card placed on the back of the preceding pocket carries the accumulated total scheduled to date. This gives at all times the open capacity or the over schedule as the case may be.

After a schedule is closed the sales department may add only such orders as the mill production office can accept with a certainty of delivery. Special promises to better previous scheduled dates are made only after the mill production office has made a special investigation to insure fulfilment of the promise given, without jeopardizing delivery of orders already scheduled.

As the various orders are produced the Chaindex cards are

stamped "inspected" or "packed" if shipment cannot be made immediately and "partial" or "shipped" if sent. At the end of the period all cards for filled orders are removed and discarded and cards for orders not shipped complete are placed in a pocket marked "carry over." Carry-over orders not produced become the most important items for the following period.

This Chaindex record gives at all times a complete picture of when each old order is scheduled, how completely each schedule

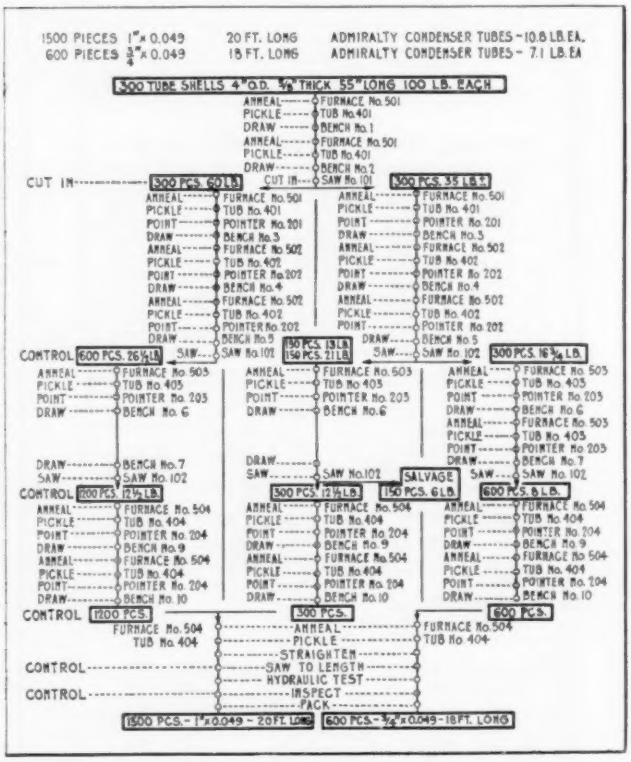

Fig. 9 Operation Chart

is filled, and where each new order can be placed in the schedule.

The record of the finished stock on hand is kept on stock cards placed in similar pockets. The drawers containing the schedules and stock records are kept in a cabinet on the desk of each schedule clerk in the mill production office. By their use he can answer promptly almost any question that may be asked.

## Operation Chart

Material is processed through the mill and shipped on the production-order form made out upon receipt of the order. A schedule clerk in the mill production office arranges for the castings to be made. He has the castings delivered with the production order to the mill superintendent, who is responsible for making shipment as scheduled.

The following of the orders through the rod and wire mill and the sheet mill is a comparatively simple matter. In these mills the material started on one production order is rarely transferred to any other production order. Thus, the different orders follow each other through the various operations to the finish. Only one dimension is changed in each cycle, i.e., diameter or thickness producing greater length. Due to the ease of coiling rod, wire, and sheet, the original casting is rarely cut into a number of pieces until finished.

Conditions in the tube mill, however, are quite different. (See Fig. 9.) Two dimensions are changed in each cycle, i.e., diameter and thickness and the ratio of these two changes must be kept within rather narrow limits. As the tube cannot be coiled, it must be cut into a number of shorter pieces as it elongates. This cutting usually occurs every second cycle. Tubing is usually ordered in a definite diameter, thickness, and length and therefore a definite weight per piece. The original casting rarely cuts to the desired weight without having a piece left over. Therefore, the material in each original casting must usually be applied on two or more orders to avoid undue scrap. Short pieces are held in salvage stock, which may later be drawn down to fill small orders when the opportunity arises. Great care must always be exercised not to allow this salvage stock to become excessive. Only careful and efficient planning can keep the scrap and salvage at a minimum and at the same time make shipment on all orders as scheduled and keep all machines and men supplied with work at all times.

This planning must of necessity be done by the superintendent of the tube mill and his assistants. As the production orders are received by him they are classified as to mixture and size of casting required. The schedule dates of the orders in each group must be watched and in due time material must be started. Material is usually started in 30,000-lb. lots, or six crane loads, each crane load carrying a work ticket bearing its lot and load number.

When a lot reaches the cut-in saw the sawyer is given a cut-in ticket telling him how many pieces to cut on each order and the weight of each piece Work tickets are given him to carry each crane load through to the finish. These work tickets give each subsequent operation, so that each operator in turn knows what he is to do when he gets the load. Each subsequent cutting is a control station and the sawyer must insure that every load in the lot originally cut-in is accounted for. He is given the original cut-in ticket to know what to expect. In case of undue loss through breakage or other cause he must see that more material is cut-in so that it may be rushed through and delay on the complete shipment avoided.

The crux of the whole procedure is the proper laying out of the cut-in so that undue scrap or salvage does not result, and the control stations at the subsequent cuttings to insure that no load or material is lost or delayed in its progress through the mill. Due care must also be exercised to see that each order is started in time to reach the packing room by the scheduled date of shipment.

## Conclusions

A careful prediction of the rate of production necessary to meet current business has accomplished the following:

1 Prompt notifications to the customer of the expected date of shipment and the fulfilment of this promise, thereby giving the customer accurate information.

2 Keeping the productive facilities elastic, thereby making delivery as near as practicable to the date desired by the customer.

3 Control of semi-finished and finished stocks, thereby making quick delivery possible when necessary.

4 Insurance that the productive capacity is not oversold, thereby avoiding dissatisfaction through delayed deliveries.

5 Keeping the sales manager informed on open productive capacities, thereby tending to keep production to a maximum in all lines.

6 Control of inventories and the acquisition of only the necessary raw materials, thereby reducing inventory and increasing metal turnover.

7 Accurately predetermining the mill hours and number of employees, thereby stabilizing labor requirements and reducing labor turnover.

8 Stabilizing production rate, thereby reducing the manufacturing cost.

## Discussion

S. P. Johnston.[4] Our problem in manufacturing aluminum bar and rod products is evidently very similar to the author's problem in connection with brass. We have, located at Massena, N. Y., a new unit whose sole function is the production of commercial rod of the type used in the screw-machine trade, etc. This unit is relatively new, having been put into operation within the past few months. Up until that time we operated on a rather small scale, as the demand was relatively light. There was no great attempt or real necessity at the time for a complicated system of production control on such a small scale, where a few people in direct charge were able to handle the mill.

The production has increased, however, so that we now are interested in putting into operation a system of production control very similar to that described by the author. Our plants are rather widely separated from our main office. At the Massena works we have a representative of the sales department, whose function is to maintain a control between the demand and mill supply. Orders are sent to the mill as received through the various sales offices, and the schedules are made up at the mill. We schedule on a weekly basis, and an attempt is now being made to evaluate our capacity in various classes of production, so that we may plan to put on schedules approximately 80 per cent of our active capacity and reserve the balance for rush orders.

At the present time the schedule of our capacity is somewhat in excess of the demand, so that orders are placed on the mill schedule almost immediately. We maintain in the mill itself a planning section which receives schedules from the main planning division and is responsible for getting them out. We use a "Lot Ticket" scheme, whereby as the orders are received in the mill, the various operations are listed by the planning department, written up on a "Lot Ticket," and dispatched to the various operations.

We maintain control stations where weights and various dimensions are checked. We do not maintain any stock of finished rod at the mill other than a small amount of standard sizes which accumulate due to the overages in production. At the present time, however, we are building up a warehousing scheme which we hope will go a long way toward stabilizing production in the mills. Warehouses are being set up at various points throughout the country, and the demand at present indicates that certain standard sizes can best be carried in warehouse stock.

At the present time we deliver from the mill, on average-size lots, in from three to four weeks. We have had difficulty in the past in meeting delivery promises, but at the present time we meet approximately 90 per cent of our promises.

William Kushnick.[5] The writer's company employs only about 300 people. The control system in use has worked during the last six months to a 95 per cent fulfilment of promises made. Promises are made by the week in about 50 per cent of the orders, and to the day in the balance. If a customer specifics to the day, an effort is made to deliver on the day desired. Our usual estimates of delivery are from two to three weeks for a manufactured order. About 60 per cent of our orders are filled out of stock within 48 hours.

In the setting of the production program, the sales department is not consulted. The sales department knows very little as to what quantity of sizes and styles it is really going to sell during a season. We have been able to assist the sales department by an analysis of our past shipments and by a study of business conditions that directly or generally affect us. In this way, the production department has in a sense set the quota for the sales.

As for the operation of the control system, the production manager has studied the capacities of the various departments and the units in those departments. He knows from the charts and records just where each department and unit stands in the amount of work ahead. Accordingly when an additional order is placed he makes the necessary additions to his records and sets the production schedule for it. Each department is scheduled by specific dates. Each unit in the department is scheduled about a week in advance. From the hourly and daily reports the production manager is able to follow the schedules and see that promises are kept.

Hugo Diemer.[6] The writer has visited many plants in recent years, and has gone over their methods of production control. The outstanding point, that all of us have to learn from this paper is that control of production with a minimum of investment in inventories is today not a thing to be worked toward, but a thing that is actually being practiced. Programming, planning of material, plans of operation, predetermination of work assignments, and all these other factors and statistics make this work much simpler than it was years ago. Further, the production budget, financial budget, and sales quota are practical and have far more close coordination than ever before.

W. R. Clark.[7] F. H. Calhoun, production control manager of the Goodyear Tire & Rubber Company, presented a paper at the Rochester meeting which contained several things that could have been embodied in the present paper. The thing of interest was that a rubber industry had worked out a scheduling system which, in many respects, could have been taken bodily and put into a brass mill. Mr. Calhoun said, in effect, that the various functions essential to production control include ordering and control of productive materials, the issuance of schedules, the dispatching of materials through the different processes, the stocking of raw and finished materials, and transportation and shipping. The function of the production-control department at the present time begins with the ordering of the materials required in the production of the various products manufactured. A yearly estimate is developed by the sales department, which outlines the probable requirements for each product manufactured by the company. This estimate is revised monthly to meet changing conditions in sales demands. Occasionally sales increases or decreases on certain products may largely exceed previous plans. The factory decides whether the tentative program is possible. The production-control division regulates the inventory on all productive materials. From the above tentative production schedule, a purchasing budget of materials is prepared.

Every one of those statements could be put bodily into the present paper, covering the control we are using in a brass mill today. It is very interesting that the rubber industry so closely parallels our efforts on a material which is manufactured in a somewhat different way.

In the rubber industry the process is a semi-continuous process. Most material started in process at the beginning of the week is finished before the end of the week. In the manufacture of brass, however, frequently materials are in process two, three, and four weeks, because in some cases there are hundreds of operations performed, particularly on smaller sizes. A large number of alloys are used. There are a large number of rolling or drawing operations, a large number of heat treatments, all

[7] General Works Manager, Bridgeport Brass Co., Bridgeport, Conn. Mem. A.S.M.E.

of which take time. There are a great many varieties of hardness or softness also, and all of these present a wide variety in the sizes, gages, widths, and lengths, a multitudinous amount of detail which makes proper scheduling control in the factory extremely difficult.

R. E. Flanders.[8] The writer's company manufacturers four or five different machine tools, and monthly determines how many units a week it shall build of those products. The rough-stock inventory, the size of the lots of work in process, and the finished-parts inventory are all determined on these standing orders, based on the output per week that has been set for that monthly period.

Every three months we go over the predetermined cycle or orders for parts in the shop. At some predetermined date in each three-month period an order is written out and put into the shop for each particular part in that program. That part may go into one, two, three, four, or five of the various machines we manufacture. It may go into one once, in others twice, and in others not at all. In any event, the number of pieces that are going to be required for the rate of production set at that time is determined quite definitely.

When the time comes to put orders for the parts into the shop, the stock clerk who makes out the order goes to the stockroom and counts the number of pieces in the bins. For the given rate of production on all machines manufactured there should be a certain number of pieces in the bins at that time. If there is more than that number of pieces, the amount of the shop order is decreased by the amount of excess. If less, the shop order is increased by the amount of the deficit. The lot of work goes through the shop, is finished at the predetermined time, and goes into the bin.

The number of parts that should have been in the bin when the count is made is such that when the new lot arrives in the bin it should find a half-lot in reserve waiting for it. In other words, we carry half of a three months' supply as a permanent margin. That reserve runs up and down with the predetermined schedule. We depend on the half-lot in reserve to enable us to change the rate of production at any time without having to wait for the three months' schedule to run its course and come around again.

Our rejections are expected to occur before they get to the stockroom, not afterward. The half-lot is a sort of safety valve for contingencies. In the same way, the purchasing agent is supposed to keep in reserve a half-lot of raw materials. This includes castings, for instance, or a half-lot supply of bar stock and similar materials, so that there always is a reservoir of a half-lot to take care of spoilages, sudden increases in production, etc. We thus are free to take care of emergencies, and also to change the schedule within limits at any time and still run the shop on standing orders.

Not a piece of paper passes between the production office and the purchasing department or the stock clerk, other than the monthly statement of the number and kind of machines we are to build per week. We have done away with stock records, and we run on standing orders instead of making a special case of every item of production in the shop.

This plan has proved exceedingly successful with a small volume of production, when difficulties would be most apt to appear. We live in the hope of applying it before long to a much larger volume.

[8] Jones & Lamson Machine Co., Springfield, Vt. Mem. A.S.M.E.

David B. Porter.[9] One of the problems mentioned by the author is the coordination of sales with production. We have found that there is no coordination whatsoever until a sales schedule is finally worked out in harmony with the mill's capacity to produce. After the schedule is made, it can be charted by means of a Gantt chart. The sales department then can watch by means of this chart the exact progress of manufacturing; and furthermore, the amounts of orders for the different lines of goods are clearly visible on this chart.

In a certain case when we first drew up the chart, some lines were oversold half a year ahead, and other lines were not sold more than a few weeks ahead, showing a very unfavorable condition. The charts were blueprinted weekly and sent to the sales department, where they were used to direct sales in accordance with the schedules shown.

Arthur Brewer. Mr. Johnston and Mr. Kushnick both spoke of the method of promising deliveries within a particular week and on a specific day. We use both methods. If the customer does not specifically request a date, we promise to the week. We call it a "schedule promise." When he particularly asks what day the goods will be shipped, we give the day, which we call a "firm promise." These are handled with a little more follow-up than the "schedule promises."

In regard to the percentage of kept promises, our "schedule promises" are fulfilled between 90 and 95 per cent. Our "firm promises" are probably kept to nearly 99 per cent. I just last week authorized the expenditure of a sum of money to give the mill foremen a dinner. Two mills had just had a competition. The foremen of the mill first to go ten weeks without a broken promise were to have a dinner. One mill had gone 21 weeks and the other had gone 15 weeks. They went so far beyond the goal set that we gave them both a dinner.

Mr. Kushnick also said that they did not consult the sales department in making up schedules. We did not use to do this. We used to make the schedule up in the production office, but I was convinced that it could be improved. The production men are usually pessimistic with regard to the ability of the sales department to secure orders, while on the other hand the sales department is very optimistic. I believe the best way is to get your optimists and pessimists together and discuss the question. Then, I think, you can strike a closer, truer production schedule than when you allow either one or the other to set it.

Papers have been delivered this morning in regard to the matter of setting budgets and how they can be controlled. We have had budgets for a good many years. In regard to the sales budget, the tendency has been with the sales department to say when business is poor, "What are we going to do—there aren't any orders?" but when business is good—"Aha, see us! See how we bring in orders," and then hound the production department to get them out. By getting together to discuss the matter the sales department has realized much more intimately the necessity of getting orders for certain lines to make a well-rounded-out production and to keep each unit producing. Of course, business conditions control this more or less, but they can do something to help out under all conditions.

I am glad to hear the various statements in regard to the use of Gantt charts. We have not used many charts in connection with the sales department, because our men have been educated to read figures rather than charts. We have found that we can get our idea across better by the use of figures than we could by the use of charts.

# Some Essential Principles for Budgetary Control

By HAROLD VINTON COES,[1] CHICAGO, ILL.

*This paper presents in condensed form many of the essential principles for the application of budgeting to a business and the effective means for control. Some of the means for securing budgetary control are shown in charts and statements of the following: (1) fundamental operating relationships, (2) comparative results of operation for different sales volumes, (3) manufacturing expense budget, (4) indirect labor control, (5) sales and production coordination, (6) sales quota, (7) department quota, (8) comparison of operating ratios.*

THIS paper is presented with the idea of endeavoring to reduce to as few words as possible many of the essential principles for the application of budgeting to a business, and the effective means for control.

*Coordinated Intelligence*

Utilize those methods that will combine effectively the coordinated intelligence of the entire organization behind a predetermined plan.

*Analysis*

Analyze past operations, past performance, past expenditures, sales, etc. in fact all those phases of the business that it is proposed to budget.

*Synthesis*

Build up from the facts developed by analysis the trends and tendencies of the past.

*Judgment*

By rational judgment ascertain and isolate those factors that will influence the course of the business in the future.

*Initial Control*

Ascertain the places where control can be most effectively obtained initially in the method, procedure, recording, and performance.

*Operating Ratios*

There is no uniform set of standard ratios expressing the various fundamental relationships between expenses and sales, manufacturing expense and cost of sales, etc. These must be determined for each individual business from the study of past records, and then checked against such ratios for the industry or important units in the industry as can be obtained. The application of these previously determined ratios then to the various items of expense in various divisions of the business will constitute the budgeted expense items.

*Relationship of Phases in Business*

Develop the fundamental relationship between the various phases of the business, such as ratio of manufacturing expense to net production, to net sales, distribution expense to net sales, and the like.

[1] Vice-President and General Manager, Belden Manufacturing Company. Vice-President and Chairman of Finance Committee, A.S.M.E.

Contributed by the Management Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. For discussion see p. 10.

*Adequate Accounting*

A prerequisite to successful budgeting is adequate accounting and statistical records, for budgeting is dependent upon all the recorded data of regular routine wherein past performance may be determined and future possibilities outlined.

*Organization*

Realign the duties of the organization so that duties and functions are logically grouped.

*Corelationship of Activities*

Budgetary control correlates the activities of the various functions of the business through executive control to prevent over, undue, or lack of emphasis on some important phase of the business.

FUNDAMENTAL OPERATING RELATIONSHIPS

| Ratio | Year 1922 | 1923 | 1924 | 1925 | 1926 | Max. or Min., per cent |
|---|---|---|---|---|---|---|
| | Per cent | | | | | |
| Cost of Sales / Net Sales | 79.9 | 79.2 | 78.1 | 77.8 | 80.1 | 75 |
| Mfg. Expense (Burden) / Net Production | 29.4 | 24.0 | 26.8 | 26.1 | 23.5 | 22 |
| Mfg. Expense / Net Sales | 24.5 | 22.0 | 24.3 | 24.7 | 20.2 | 20 |
| Raw-Material Inventory / Net Production | 40.1 | 42.0 | 41.9 | 39.8 | 38.9 | 35 |
| Process Inventory / Net Production | 30.1 | 32.0 | 31.0 | 29.9 | 29.2 | 26 |
| Direct Material / Net Sales | 37.5 | 35.2 | 37.2 | 38.5 | 39.1 | 35 |
| Direct Labor / Net Sales | 23.4 | 22.8 | 20.9 | 21.7 | 22.0 | 20 |
| Indirect Labor / Direct Labor | 47.0 | 46.5 | 46.1 | 45.8 | 45.2 | 40 |
| Finished-Goods Inventory / Net Sales | 10.8 | 10.4 | 10.1 | 10.5 | 10.0 | 10 |
| Total Inventory / Net Sales | 24.3 | 24.0 | 23.8 | 24.2 | 23.0 | 20 |
| Fixed Expense / Total Mfg. Expense | 28.1 | 28.3 | 27.9 | 27.2 | 27.5 | 25 |
| Working Capital / Net Sales | 35.1 | 34.8 | 35.5 | 34.2 | 33.1 | 30 |
| Gross Profit / Net Sales | 21.1 | 20.9 | 21.9 | 22.2 | 19.9 | 25 |
| Selling Expense / Net Sales | 10.9 | 11.0 | 11.4 | 12.2 | 12.5 | 11 |
| Net Profit / Net Sales | 4.3 | 4.7 | 5.1 | 5.5 | 3.9 | 5 |

*The Budget and Executives*

The budget can in no way replace skilful executives, but in their hands it is an exceedingly useful tool for modern management.

*Flexible Standards*

The expression of results for the various phases of the business, for the departments, subdivisions, etc. should be in such terms that they are suitable to the various elements, yet flexible enough to permit ready adjustment to ever-changing conditions.

*Determination of Standards*

Carry the analysis far enough back over a sufficient period so that the law of averages, the swings or cycles, trends and tendencies can be fully developed; correct for those influences

that were purely accidental, so that representative standards may be developed.

*Segregation of Costs*

Segregate all items of expense or cost into three groups:

1 Fixed or non-variable
2 Semi or partially variable
3 Full variable.

*Break-Even Point*

Develop the break-even points (points at which no profit or loss is sustained) for the expenses as budgeted for the various departments, and the corresponding volume of sales per class of product.

*Production Capacities*

Regardless of sales volume, determine the production capacity of the plant and break this down by departments, by sections, in well-balanced relationships. Determine it also by classes of product.

*Relationship Between Productive Capacity and Sales Volume*

Through the market surveys determine the minimum volume at those price levels that the market will take up, which will absorb the greatest proportion of potential productive capacity.

*Product Demand*

Budgeting is again dependent upon a knowledge and relationship between:

*a* Demand for the given product and demand for the product of the entire industry
*b* Demand for the individual product and its relationship to the demand for similar articles similarly marketed
*c* The purchasing power for which the demand can be sustained.

*Budget Period*

Cover the longest period with the minimum business hazard. Usually the period can be the longest for those businesses having the least hazard, and must be shortened as the business hazard increases. Its determination is fundamental and is largely contingent upon several factors, such as:

*a* The business risk
*b* The stability of the market
*c* The method of financing, production and inventories
*d* The schedule period of production
*e* The duration of the reporting and accounting period
*f* The adequacy of statistical information as to past performance and transactions
*g* The merchandising inventory turnover period
*h* The seasonal or periodical demands and fluctuations.

*Revision of Budget*

Budgets should be checked, compared, and revised monthly.

*Control of Expense*

Control can be obtained by frequent comparisons—not less than once a month—between actual and budgeted expenses, the budget of course adjusted for the legitimate expansion or contraction in sales volume or production that has occurred contrary to the predetermined budget for the period.

*Limits*

The budgets as adopted constitute the standards of performance for the period determined, and establish limits for the expenditures of each division and section of the business, but should not be exceeded without permission from the properly constituted authority.

*Forecasts*

Forecast all those expenditures, be they capital outlays or expense items, that it is proposed to control by budgets, or that will affect the phase or phases of the business to be controlled by budget procedure.

*Preparation of and Responsibility for Budget Estimates*

The source of information should be from the logical divisions of the business, and the responsibility for the origin and accuracy should be lodged with those charged with the responsibility for the performance of the aforesaid divisions or sections thereof.

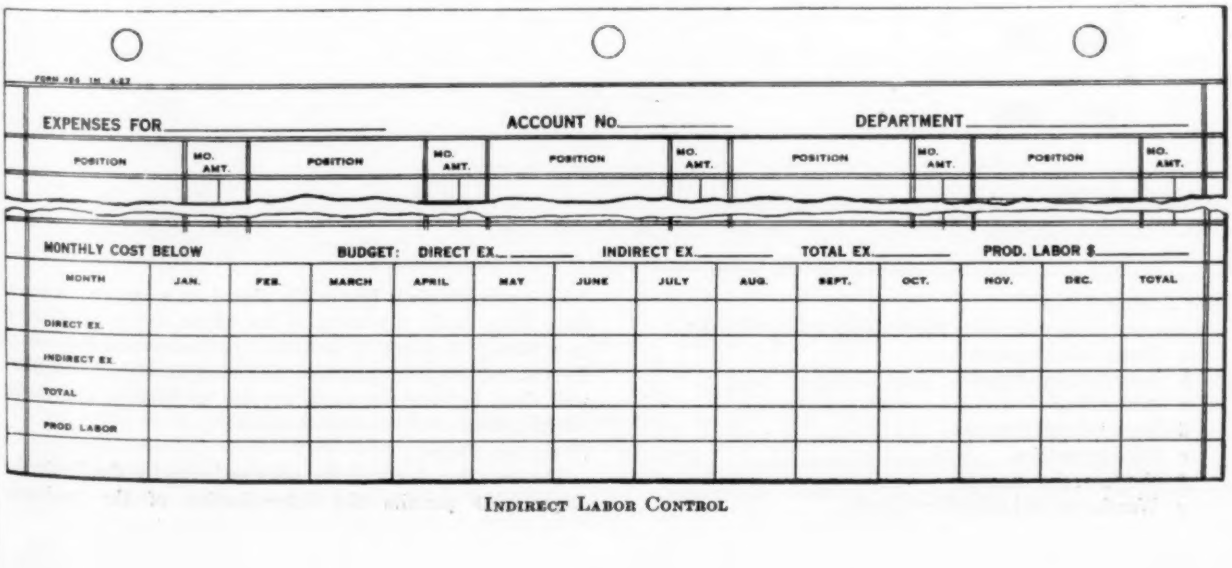
*The Sales Estimate or Forecast*

This is based upon information from three sources:

1 The amount and character of previous sales—analyzed
2 The present and future market conditions, the trade situation—market analysis
3 The executive plans, policies, and administrative expense of the business.

*Balancing of Production and Sales Demand*

Proper sales forecasting coupled with adequate inventory control permits the application of the principle of balancing production with sales demand.



EXPENSES FOR ____ ACCOUNT No. ____ DEPARTMENT ____

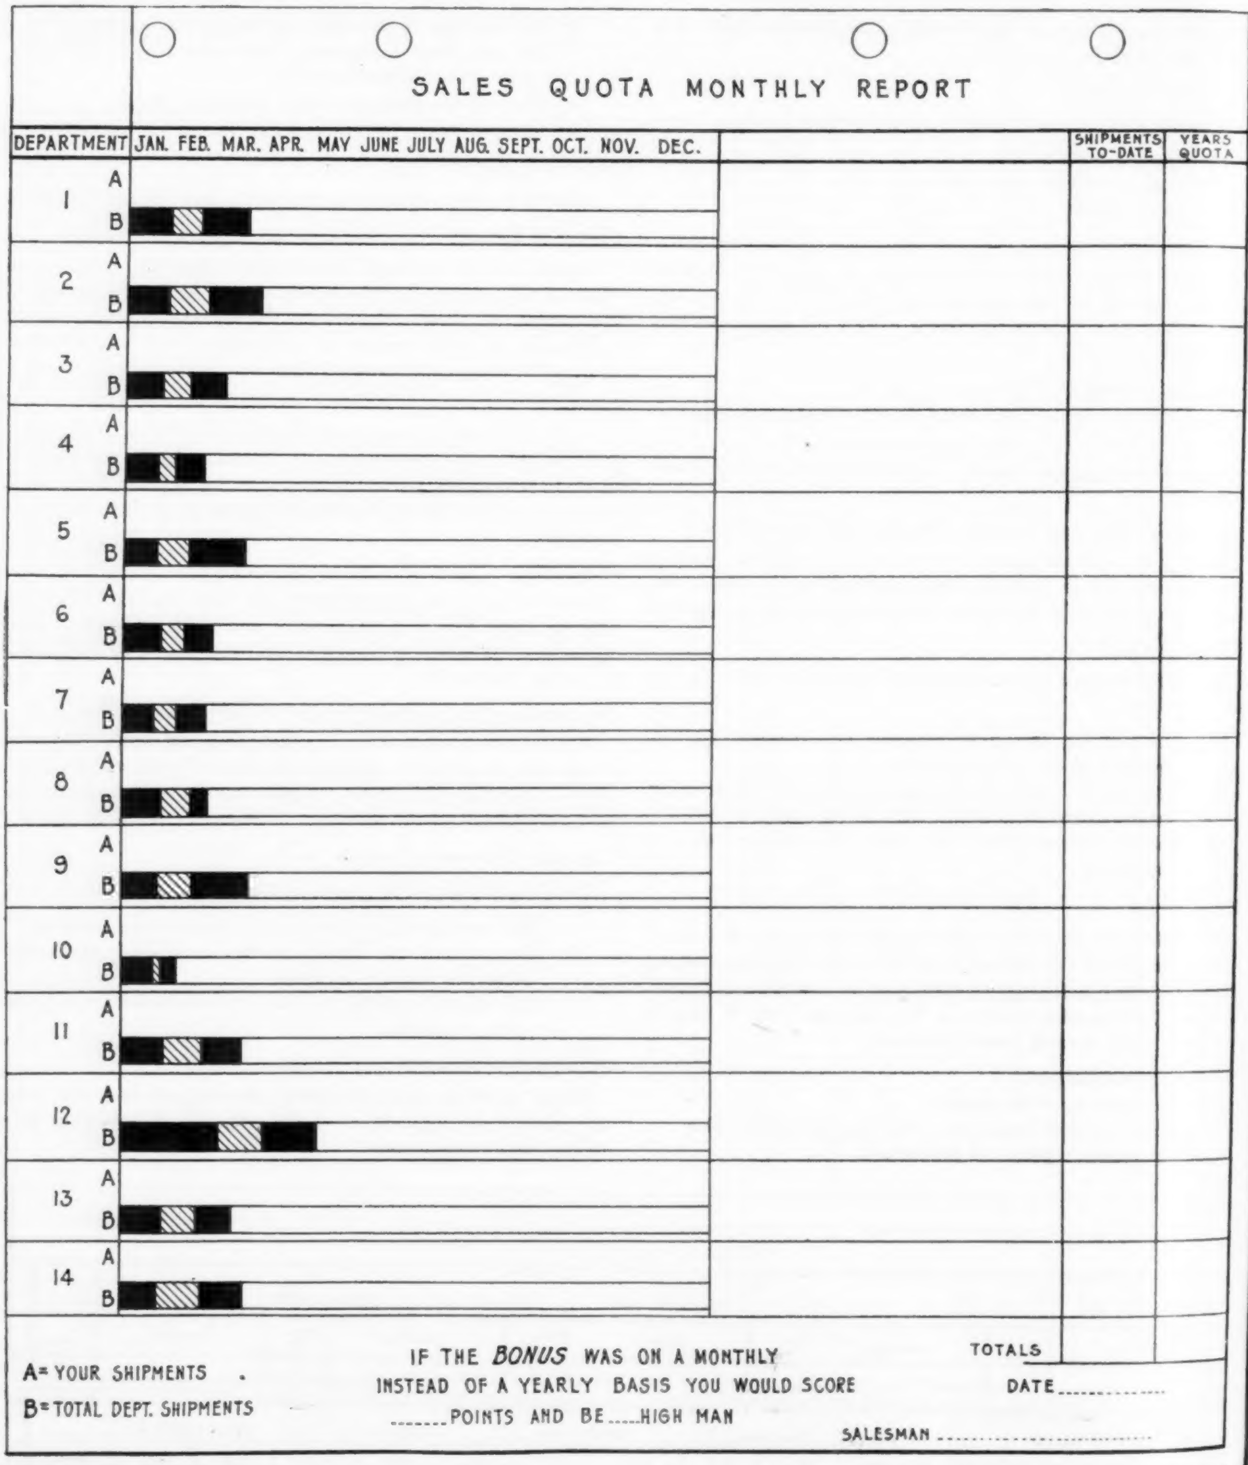
Indirect Labor Control



*Sales Expense Budget*

It is aimed to secure proper relationship and control of:

- *a* Direct sales expense
- *b* General sales expense
- *c* Advertising
- *d* Branch-house expense
- *e* Sales promotion
- *f* Foreign sales expense
- *g* Warehouse and shipping expense.

Undue emphasis is frequently placed on some one or two of these items to the detriment of the others, and to the business as a whole. Advertising and sales promotion are frequent offenders. A properly prepared and considered budget will reveal these facts, show which are out of balance, and permit bringing the several items into balance.

*Production Budget*

The breaking down of the sales estimate by the Production Department permits the determination of the production

DEPARTMENT QUOTA MONTHLY REPORT

| TOTALS | | | | | | | | | | | | | | |

DATE ................ 1927

estimates in total, except for goods made to special order. Ordinarily it is impractical to budget in advance special order production per se.

The principle of scheduling is then used to insure production in sufficient quantity at the proper time to satisfy the estimated sales demand, which is predicated upon:

*a* Operation analysis—from specifications of product

*b* Schedule of productive equipment with capacity per unit.

This may show that:

*a* Sales forecast exceeds present productive capacity under normal operation

*b* Sales forecast is less than present productive capacity under normal operation

*c* Sales forecast approximates present capacity under normal capacity,

and will necessitate reconciliation of either one or the other, depending upon the financial program.

This brings in inventory control, since it is usually impossible to so accurately forecast sales demand and schedule production as to have the two so synchronized as to accurately meet sales demand.

Excessive production beyond immediate sales demand runs up the inventory and ties up working capital. Inadequate production causes poor service to customers and lost sales, and consequently lost income. Hence adequate inventory control is of prime importance.

*Balanced Inventory*

Properly apportioned and balanced inventories are then a prerequisite to satisfactory budget operation, and these are brought about by adequate and comprehensive budgetary control.

various classes of product. By then stating the dollar volume in the sales estimates, adjusting for cost of sales, and applying the labor ratios, a fairly approximate labor budget can be set up.

By using similar ratios for the relationship of direct to indirect labor, the indirect labor budget can be similarly prepared.

*Manufacturing-Expense Budget*

Where centralized production and standardized goods for stock are not the rule, probably the most practical method of dealing with the manufacturing expense is by the application of the principle of standard overhead or burden rates. Here a reserve is set up and over-absorption of burden during peak or overnormal operations is credited to the reserve, and during dull seasons, when operating at less than normal capacity, the deficiency is debited from the reserve, the whole being set so as to balance out for the year's operation.

MONTHLY COMPARISON OF OPERATING RATIOS

| RATIO | JAN. | FEB. | MAR. | APR. | MAY | JUNE | JULY | AUG. | SEPT. | OCT. | NOV. | DEC. |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Net Sales Billed to Quota | | | | | | | | | | | | |
| Cumulative | | | | | | | | | | | | |
| Distribution Expense to Budget | | | | | | | | | | | | |
| Cumulative | | | | | | | | | | | | |
| Administrative Expense to Budget | | | | | | | | | | | | |
| Cumulative | | | | | | | | | | | | |
| General Expense to Expense absorbed | | | | | | | | | | | | |
| Cumulative | | | | | | | | | | | | |
| Manufacturing Expense to Budget | | | | | | | | | | | | |
| Cumulative | | | | | | | | | | | | |
| Manufacturing Expense to Expense Absorbed | | | | | | | | | | | | |
| Cumulative | | | | | | | | | | | | |
| Factory Operating Capacity to Normal | | | | | | | | | | | | |
| Cumulative | | | | | | | | | | | | |

*Material Budget*

Since the principle of balance of stores is applied satisfactorily for the finished goods inventory control, the same principle can be applied to balance of stores records for raw material.

*Labor Budget*

This is the most difficult budget to prepare, particularly where goods made to order are a large proportion of the total production, since operations and combination of operations vary over wide ranges. The principle of standardized operations is applied, and where this is done one hundred per cent the preparation of the labor budget ceases to be a difficult matter.

Frequently an approximate control can be obtained by using predetermined ratios of direct labor cost in the cost of sales of

For control purposes the actual expenses should be compared, not only with the normal budget but also with the normal budget adjusted to what it would be for the actual capacity operations. Under these conditions control can be effectively obtained.

*Plant and Equipment Budget*

This is to prevent:

1 Overexpansion
2 Force careful considerations of capital layouts
3 Preserve proper relationship between retirements, replacements, maintenance, and depreciation reserves
 a Repairs charged to current expense—standard maintenance and standard maintenance budget

*b* Betterments (improvements) and additions are set up in the capital budget.

This budget would then show:

1 The estimated cost of new equipment installed and in place
2 The depreciation and anticipated repairs on new equipment
3 The depreciation and anticipated repairs on present equipment.

*General and Administrative Expense Budgets*

These to cover such broad classifications as:

*Financial Budget*

This is set up for the correlation of income and expenditures:

*a* An estimate of cash requirements, predicated upon the programs as set forth in the preceding budets
*b* Estimate of cash receipts. This is predicated upon:
  1 A relationship of sales to collections
  2 Other sources
  3 Bank loans—with program therefor.
*c* An estimate of cash disbursements:
  1 Material purchases (accounts payable)
  2 Factory payroll

ADMINISTRATION-EXPENSE SCHEDULE

*a* Executive
*b* Service or auxiliary departments
*c* Financial
*d* Non-departmental or corporate expense,

and these are predicated upon:

1 A proper main classification logical for the organization as set up
2 The incidence of these expenses and the responsibility for their origin and supervision
3 Sufficient sub-classifications to enable detection of variations and permit the focusing of responsibility.

3 Factory overhead expense (manufacturing expense)
4 Distribution expense (sales expense)
5 General and administrative expense (executive)
6 Non-departmental (corporate)
7 Capital account (new equipment, plant, etc.).

*The Forecast Balance Sheet*

1 Assets and liabilities
2 Profit and loss.

These two statements, then, when compared with the actual results of operation, show what the effect has been of the individual budgets and quotas on the operation of the business as

a whole, and where these have fallen below or exceeded actually the predetermined balance sheet and profit-and-loss statement.

From this master budget and individual budgets the executives can then determine why the predetermined programs fail to be realized and can apply the corrective measures required to bring them in balance. This may result in revisions of many of the individual budgets to bring this about.

*Reports*

Suitable reports should be set up giving estimated forecasts of predetermined budgets compared with actual results:

These reports showing the comparison between the estimated or forecast performance are taken as standard, and the actual performance renders it possible for the executives responsible to enforce the budget and keep operations correlated and in balance.

They also serve to show what plans must be made for the future for financing, for production, for sales expansion or curtailment and the future plant requirements.

Some of the means for securing budgetary control are shown in the accompanying statements and charts:

1 Fundamental operating relationships

NOTE: For some of the material for this paper the author wishes to acknowledge his indebtedness to "Budgetary Control," by J. O. McKinsey, "Organization and Budgetary Control in Manufacturing," by Fordham and Tingley, "Financial Handbook," by R. H. Montgomery, "Management's Handbook," by L. P. Alford, *Manufacturing Industries*, *Industrial Management*, and the American Management Association.

# Budgetary Control

By J. P. JORDAN,[1] NEW YORK, N. Y.

*In the influence held by a chief executive over the mentalities of his subordinates, whereby he secures from them the greatest possible producing effort, lies the real secret of his success. Many executives hold this influence by sheer personality. Others hold it by a combination of personality and the careful selection and provision of various schemes whereby the subordinates themselves are more or less automatically spurred on in their efforts.*

*It is a well-recognized fact that we are a nation of aggressive people; that we take business chances as a matter of course. The widespread interest in sports—golf, baseball, football, tennis, boxing, polo, etc.—is evidence of the sporting angles of the average American mind: the apparent evidence of a desire either to indulge in or to become interested in a game.*

*Budgetary control supplies to every one in any kind of a business institution a species of a game. The setting of quotas of performance and budgets of expense brings out a cool and calculating thought of the future and what it should yield. The daily watching of the current transactions becomes as fully absorbing as the watching of the electric score board of a World's Series game. A par has been set and must be beaten.*

*The psychological effect of budgetary control is its greatest asset, and in this feature alone it takes its place as perhaps the most valuable of all more or less mechanical management aids.*

THE type of management which pays strict regard to psychological effects in controlling the various operations of a business institution is almost invariably successful. While it is often said that since the war, management has been obliged to control in a manner different from that which obtained before the war, it is probably a fact that the most outstanding cases of successful management before the war were those which employed exactly the same methods as are successful today. Since the war, management in general has been forced to give far greater consideration to the human factors of business than before.

We have heard a great deal about "Golden Rule" management, cooperative management, committee management, legislative management, and all such types which have been more or less successful. If one would analyze the various-named types of management which have been used, it is believed that the final conclusion would be that the outstanding successes have been those where careful psychological analyses became the guide of the executives who composed the successfully managed business, rather than some specific form of management. It is somewhat immaterial as to the exact methods used in applying to a generous degree the results of careful consideration of the psychology of each situation. At no time in industrial history has it ever failed to be clearly apparent that an organization conducted with due regard for the upbuilding of the various key men in the organization is the true method of building a safe, stable, and permanent industrial structure. The prime consideration in the upbuilding of an aggressive and successful organization is a leadership which permits nothing but absolute fair play to every one in the organization, and which further permits nothing but absolute cooperation between the various departments of the business, firmly and effectively coordinated by a chief executive whose whole endeavor is to build up every responsible individual in every possible way, thereby automatically elevating the office of chief executive to a plane much higher than otherwise could be accomplished.

### Too Few Executives Study the Psychological Factors of Organization Procedures and Personnel Problems

Too few executives study the psychological factors which enter into their organization procedures and into the personnel problems which are ever present in both large and small organizations. Too few executives realize that every human being, no matter whether in a high position or a low one, takes an intense pride in his work, provided his scope of responsibility is so clearly defined that it can be regarded by each individual in a very personal way.

It is exactly this feature which is the basic consideration of bonus incentives, profit-sharing schemes, and all other such plans to bring out a greater personal interest on the part of each individual participating. A worker at a machine does not think half as much of the additional bonus which he makes in his pay envelope as he does of meeting and beating a fixed standard time. Not long ago the author was told that during the preliminary stages of the installation of a bonus plan, and before the workers, or even the foremen, knew what was coming, a gang boss in a foundry became so enthusiastic over meeting and beating the standard times set for the various tasks of his gang that he nearly got into trouble with his men on account of driving them so hard to make a record. Needless to say, when the bonus scheme was announced this enthusiasm not only kept up but it increased to a very remarkable degree, with the result that his particular gang achieved some very wonderful records of performance. The secret in the instance just recalled proved to be what is usually found in the majority of cases, namely, that the psychological effect of making a game out of every-day work has in itself a tremendous measure of merit, even without promise of extra financial reward.

Budgetary control is a mechanism which should be thoroughly understood before it is employed by any management. If an executive who has little use or consideration for psychological effects should think that the installation of a mechanism such as budgetary control will, in itself, produce any great results, he had better stop before he starts. It is in such cases as these where we should find a constant stream of complaint if, and when, the actual results differ to some extent from the budgeted expectations. In these cases, budgetary control becomes simply a guess, and a questionable allocation of actual results against the guess. Mountains of complaint will pile up to the effect that some one was a poor guesser, or else that the accounting department is incompetent because it does not properly allocate actual results against a more or less misguided set of guesses.

All executives who fail to appreciate that budgetary control has its greatest value in its psychological effects on the organization as a whole, are absolutely lacking in one of the greatest essentials of successful management. This not only applies to budgetary control but to any other mechanism for the assistance of management in the proper conduct of business.

### The Great Psychological Value of Budgetary Control

If we consider briefly some of the high spots in setting up a budget, we may obtain a clearer idea as to the great psychological value of budgetary control. In every industrial or commercial institution the forecasting of future operations depends primarily

---

[1] Consulting Industrial Engineer, Stevenson, Harrison & Jordan. Mem. A.S.M.E.

Contributed by the Management Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of The American Society of Mechanical Engineers.

on general economic and market conditions. This means that the sales department—that department whose ear is on the ground at all times for future business—must make up its mind to two things: first, as to what it considers the possibilities of business will be for a certain period ahead, and second, as to what portion of the available business it feels it can secure. This is usually built up starting with the salesmen, who are far-flung in the field and who understand their own local conditions; then through branch offices where the various salesmen's figures are combined into the branch expectations; and from there to the main office where the expected business is assembled into one group by classes of product, and even units, if possible. This final assembly will become the quota section of the budget, and as these quotas have been carefully looked over and checked, it is quite reasonable to suppose that every individual in the sales department subscribing to these quotas is prepared to fight to the last ditch to produce the business which he has conservatively stated is possible of accomplishment. Does this not have a most powerful psychological effect on every member of the sales force?

These quotas then become the basis of the manufacturing operations. The raw-material requirements are arrived at by breaking down the various specifications of the product required. This gives the purchasing department its cue for the procurement of materials. The manufacturing department computes the force which it needs to produce this business after taking into consideration stocks on hand and delivery requirements. It can arrange its schedules to best advantage for the speed of operation indicated by the quotas submitted.

Should the manufacturing department, on account of its cost of production, feel that the quotas as furnished are not in line with best practices of manufacturing, it can submit to the management its thoughts in this direction, and the sales department can be approached as to what means can be taken to obtain a larger quota should the original one be too modest. The purchasing department likewise may call attention to the fact that the quantities specified cannot be purchased to best advantage, and the management must therefore decide with the purchasing department upon whatever relief may be thought best.

When all of these figures are assembled into a general budget, the controller's or budget department will be able to set up the general results and show a very complete picture of what would happen if the business operated on the basis of the quotas as originally set up by the sales department. A forecast profit and loss would be set up, and the treasurer's department, likewise, could see what funds would be required, how the accounts receivable would accrue, and what the financial state of the business would be at any time during the budgeted period.

The object of these brief references to the high spots of budgeting is simply to bring out the fact that every key man in the organization is *required* to visualize the future, to go through the moves of anticipated transactions before they have been begun, and to live through a specified period of future operations to such an extent that he will become thoroughly imbued with the necessity of making good on the figures which have been set up in the budget. The effect on the mind of each key man is tremendous. He assumes personal responsibility which otherwise could not possibly be assumed, and very few men today will shrink from assuming this responsibility when they are given the opportunity. If this does not involve psychology, then the author knows nothing that does.

When the budgeted period begins, the greatest psychological value of budgeting begins to become apparent. Watching the score of a World's Series game becomes child's play as compared to watching the score of actual results as they are set up against carefully budgeted expectations. In the case of the World's Series game, a cigar or a new hat may be at stake; in the case of the business game there are stakes of different kinds to be won or lost: first, the stake of accuracy of judgment of business and market conditions; second, the accuracy of judgment as to what the selling organization is capable of securing; and third, the accuracy of judgment as to how much it will cost to secure this business. It is a matter of pride to those charged with the duty of setting up the budget to make good and to beat the quota for quantity of business or the budget of expense as originally set up.

In the manufacturing, purchasing, treasurer's, and all other departments the same principles are involved. If the manufacturing department starts out on a schedule and is supposed to reach certain costs, it is the greatest game in the world to make good and beat the objectives which have been set up. If raw materials have been budgeted at a certain figure, the purchasing department will use every effort to beat these budgeted figures. If the treasurer's department think it will be necessary to borrow some money, they will strain every nerve to push forward their collections in order that the amount to be borrowed shall be less than that budgeted. In fact, throughout the entire organization the humdrum routine of every-day business becomes a live and interesting game, and a game of intense seriousness.

Now, go a step further and supplement a well-organized budgetary control by a scheme of bonus incentive whereby all individuals concerned can profit individually if the expected figures are equaled or beaten. The class of men occupying the higher positions, and even lower than the higher positions, will respond to the stimulus of budgetary control even if no incentives are provided. It seems to be a natural instinct in every American to want to play a game or to become interested in games which are played. No people in the world support to such an extent the various sports as do Americans. The number of persons who listened to the radio account of a certain boxing match a short time ago probably ran into the millions, and judging from the reports that some of the auditors dropped dead from excitement, there must be a tremendous influence exerted by our great American games.

Any management which allows the every-day transactions of business to drift into a humdrum and tiresome routine is guilty of mismanagement in the higher degree. Budgetary control is not a fancy mechanism to be indulged in by the business connoisseur or method fancier. It is a live and breathing mechanism which brings into play the vision, imagination, action, and whole-souled interest of every individual in an organization who is privileged to become involved in any way with its operation.

## Discussion[2]

H. L. Freeman.[3] An estimate is nothing more than a budget that gives in considerable detail the final figures that go into the general budget. This estimate is prepared by comparison with previous costs and with the information available at the time. The budget, of course, is intended to cover a year's work, and generally without revisions.

The design and construction of the separate jobs covered by the budget take place throughout the following year. An appropriation made from the budget estimate for a particular job based on preliminary information will not correspond to the latest requirements. That, of course, is one difficulty in forecasting some months ahead.

Another difficulty is that the executives, in looking over these

[2] The papers by Messrs. Jordan and Coes were presented together, and, the ensuing discussion applied to both papers. In the course of the discussion many questions were asked and answered at the time by the authors. These answers are incorporated in the closures, without being separately presented in the discussion.

[3] Cost Engineer, Dixie Construction Co., Alabama Power Bldg., Birmingham, Alabama. Mem. A.S.M.E.

budget items, generally have some self-satisfaction in cutting down the totals—presumably to save the company money. But when the actual costs are obtained, they more closely approximate the original estimates than the budget's revised figures.

The men who do the work in the field know these facts, and the psychological effect of the budget as being a goal is defeated. They feel from the start that it is impossible to meet the amounts appropriated, and so go along and do the best they can. In the case of a public-utility company, bonds can be issued for what the construction work costs, so it is a question whether or not the construction man has saved any money. This is one place where budgetary control does not necessarily produce reduced costs.

C. E. Wager.[4] The writer cannot agree with Mr. Freeman that it makes no difference whether or not the construction man estimates accurately, due to the opportunity of the public-utility company to finance capital requirements by the issue or bonds or other securities to the public. We must recognize that the cost of capital before long will be at a point where from a competitive standpoint we cannot afford to waste money in unusual and unwarranted expenditures. We must keep plant accounts down, and begin to trim interest charges as well as operating expenses.

Another thing that might be commented on is the statement to the effect that the central office apparently has a habit of reducing the estimates from the field. That is a very dangerous and unprofitable proceeding. It certainly will result in the conditions mentioned. In our own organization we always leave the estimate of the man who has the responsibility of turning out work stand as he submits it. He is responsible for the completion of the work as he estimates it.

In the matter of tolerance, particularly on construction expenditures, two different viewpoints may be taken. Assuming that we have a large project to be financed in advance, in arranging for the bond issue or other securities, as the case may be, it is well to permit the engineer to include an item for contingencies, so that the final actual cost will not exceed the estimated cost. We all know from experience that certain items will occur during the period of construction work which cannot be foreseen when the original budget is made. In laying out the financial plans in advance, contingencies must be provided for. In our own organization we weigh the original estimate, and if it is found expedient to include an item for contingencies, it is understood that no commitment will be made against the contingency item without definite authority in advance by the engineer and executives in charge of the operation. The percentage to be allowed on a fairly large project for contingencies depends entirely upon the engineer. One large plant had an item of 15 per cent for unforeseen contingencies. It is not specifically in the budget, but was fixed by the experience of the engineer. On all smaller jobs, contingency tolerances are left out of the estimate entirely, and variations plus and minus are permitted to stand without question. If the home office requires further explanation, it depends upon the nature of the requisition and the amount of the requisition. If a turbine is being repaired, for instance, the requisition might be overrun, and an explanation would be called for as to what had to be done.

C. H. Bigelow.[5] The question has been brought out a good many times that estimates for the budgets come from engineers primarily, and it is a fact that the engineers are not always able to get costs on which to base the estimates. In the writer's experience it has been a hard job to get costs for making an estimate. The hardest work of all is to get unit costs. Auditors should take that into consideration and give the engineers more with which to work.

[5] Plant Engr., Spicer Manufacturing Corp., S. Plainfield, N. J. Mem. A.S.M.E.

Frank L. Sweetser.[6] Some one has asked if there is a difference between "budget" and "estimate," inferring that estimate refers to a particular job, while budget covers the business as a whole. This question of name is an interesting one. In the accounting field we have been trying to get some standardization. Estimates, and normals, and standards, and budgets are getting closer and closer to the same meaning all the time. The subject of budget control is a broad one, which cannot be limited by any name. An estimate in one case may mean a particular job, and in another case it may mean something entirely different. While data, statistics, and such things must be available, nevertheless the human element is the most important. Are you thinking about your problems, and are you having your organization think about them? Are they thinking about them in terms of the future? Looking into the past to get comparisons will avail but little. The leaders in industry are not comparing last year at all. They are comparing something else, namely, what is to be.

H. V. Coes. It is quite astonishing to note the speed and the acceleration with which budgeting is carried out once the organization is, sold, on the plan. And one of the reasons why budgetary control is not sold to the organization in so many cases is again a psychological matter. It is because the budget is so frequently handed down from the top, and the men are told to "do this and do that." Most men like to set their own goals in their own way. They like to attain those goals by their own methods provided they do not run counter to the general rules. The game of business cannot be properly played if some one proceeds one way and someone else a different way.

There are a number of fundamental rules and regulations which must be understood by all. The principal job is to make real budgetary regulation a game. It can be so made.

With reference to tolerances in budgeting, there is in the paper a chart of manufacturing expense. At the bottom of this chart is an item "Budget Correction for Variation in Productive Labor." In other words, we cannot in our business say in March, 1928, "The product from that plant and productive labor required to produce that product will be, for example, $54,000 for the month," because we are not making automobiles. Fifty per cent of the product is made to order for some one else. When we set up a budget, we set it up on what we term a normal period, which is the result of statistical studies covering a period of years. We correct the budget from the final figures which come in for the month as compared with the actual, and in the meantime our people all know that the management will permit, informally, a reasonable variation in the budget. No percentage figures are set for the variation, because in some cases a fixed percentage would be an amount of money that would be ridiculous. In other cases it might not be adequate to cover the situation, where one budget item might be badly out of line. We do not have set tolerances, but we do recognize the principle of tolerance. The factors that are taken into consideration are: the sales rate, the classes of merchandise or product, and the productive labor. The question has been raised as to reserves for extraordinary maintenance, as for machine breakdowns, which might occur only once in several years. We attempt to budget maintenance expenses and we have been fairly successful with it. But we have extraordinary expenses which cannot be predicted. Those charges are pulled out of the regular budget, and treated

[6] President, American Management Association, New York, N. Y.

as extraordinary expenses. If the item is to be prorated over a period of years, we carry only the prorated portion in the budget and the balance as a deferred charge.

J. P. Jordan. One of the purposes of the paper was to stress the psychological effect of budgeting in an organization. To be sure, we must have more or less mechanism to carry it out. We must know how to work a budget to a very considerable degree. In the last analysis, however, that is the least part of it; all the mechanism in the world will fail if it does not carry through to embrace the actual, whole-hearted interest of every one in the organization.

Look back over the successes in business, and the failures in business, and analyze the reason for successes and failures. If you can get at the facts in any case, you will find out that the success or the failure was in direct ratio to the attention paid by the management to psychology: that is, to the attention paid by the management in man-building, in impressing every one in the work with the enormous responsibility attached to each and every job, whether it is the president of the company, or the office boy delivering mail at regular intervals around the office.

Budgetary control came into existence not long ago. It is a comparatively new thing, as we term new things today, largely rating it from the standpoint of fact that it has only just about come into fairly general use. Budgetary control has been in existence for a great many years in the best-regulated companies, but today we see it quite generally used, or at least an attempt made to use it. Why is it? It comes right up to the point of psychological effect on the organization.

Doubtlessly many will say, "Well, yes, there are lots of businesses that lend themselves to budgetary control, but my business doesn't." There is no business that does not lend itself to budgetary control. Take into consideration that a budget, so-called, is really in two parts—the performance factor, the goal in volume of sales or quota, and the cost budget or the expense of doing it. They are two very different things. For instance, there is a sales department. So many sales representatives will cover so much territory. That is comparatively easy to set up. There are certain representative branch offices. There may be a definite budget for advertising. The men are kept on the payroll all the time, anyway.

It is not so easy usually to set up quotas with the sales department. The usual cry is, "We are not clairvoyants. We cannot read the future. We cannot say that we will sell." It is difficult to get the sales department to commit itself on what it is going to do, and on what it expects to undertake. That is all wrong. It is easy to budget expense, it is difficult to set up quotas of performance, and yet we must have them for a good many reasons. The psychological effect is the greatest reason for setting a goal. The sales department may say, "Well, we may hit way off, and become laughing stocks."

Nobody will do any laughing at all because of the fact that from past records, business conditions existing at the time, from the nature of the organization as a whole, from the excellence of the product, from the popularity, from its exclusive features or simply from the fact that the organization is manufacturing a stable product with a powerful selling organization behind it, it is possible to set up a quota. There is no reason at all for any one's hestitating to give an idea of what he is going to try to sell. The best of that is, that one and all, when he sets a goal, will do their utmost to meet or beat that figure. Whether it is met or beaten depends on many factors. It is in the analysis of those factors that we get the greatest value out of budgeting.

If we sit down with whoever is responsible for having set the goal, with various individuals, far-flung, perhaps, throughout the whole organization, and analyze the expense budget to ascertain why it was not reached, we are bound to develop the reasons. Therefore the next time the quotas are set up, the next time the budget is made, we have the benefit of all those things that happened, the reason for falling off here or for increasing there, and in consequence, the next quota will be far closer than the first one.

A certain company, on the basis of the budget, set up a profit and loss account on the telegraphic reports coming in up to midnight on the thirty-first day of the year, using standard costs and standard performance in connection with the budget. The directors met next morning, the first day of January, and dealt with big problems on which the profit and loss had an important bearing. When the actual figures came along about ten days later, they were less than one per cent off from the figures set up on the last day of the year.

Such accuracy cannot be reached right away, but like everything else, that point can be approached gradually, and perfection comes along that line very rapidly. It all depends on the managerial attribute or the managerial success in guiding the minds of the various people in the organization to visualize the future, to see the benefit of setting these goals, and the great advantage that is to be had through the whole organization—salesman, plant manager, foreman, and the worker at the machine. In plants we have known for many years where budgets or quotas are set up, 95 per cent of all the workers in the plant are just as crazy to beat a mark as the manager is to have them.

One of the questions that has been asked, inquired as to whether or not budgets should be made with a tolerance, say, $100,000, plus or minus, just as an engineer would specify a dimension in the design of a machine as 1 in. $\pm 0.001$. In making a budget, a tolerance is usually taken into consideration, except that it is, perhaps, on the plus side. When an expense budget is being made up, the tolerance should be for the fellow who has to make good on it, so that he has a chance to win his game. Otherwise he is being everlastingly cut down so that he never tastes the sweet fruit of beating the figures. Mr. Coes has said, and he is correct, that the budget handed down from up above is a pretty poor budget.

After the department head has made up his budget, the manager who is considerate will put the expense budget through with the tolerance a little bit on the plus side. He will say, "I want to make you safe on this and allow just a little more there so you have something to go and come on." The inconsiderate manager will not get far. He will screw things down so hard that everybody will be disgusted. He will not allow any tolerance, and that is just as bad as the other is good. There must be a tolerance in budgets. There is no such thing as exactitude.

Another question that was raised was that of the extent to which the engineering department entered in when budgeting overhead, indirect, controllable, and non-controllable charges. It all depends on the business. Some have engineers, others have none at all. Other businesses are all engineers. The extent to which engineering departments enter depends on the extent to which the business is engineering business. There are many business and mercantile houses that have budgets. The same thing applies to the haberdashery shop, or anywhere else where expenses are set up for the year for rent, fixed help, and all other expenses, and a quota is set up in advance in order to see what must be sold during the year to come out even.

The engineer cannot spend his time more profitably than by getting all the latest literature on budgetary control, standard costs, and those things that have to do with cash in the business, and learning what they mean. With all the engineering in the world, no business can run on a business basis until it has the proper costs to back up the engineering.

# Determination of Minimum-Cost Purchase Quantities

## The Development of a Formula That Considers the Principal Factors in the Cost of Purchases

By R. C. DA .S,[1] FLINT, MICH.

IN PLACING an order the purchasing agent must consider not only price but in addition quality, delivery, and quantity. Every experienced purchase executive knows that a cheap price may prove most expensive if the quality of the material makes it difficult to process or depreciates the ultimate quality of the product; if the material is not delivered promptly, causing expensive hold-ups of the production program; if the quantity purchased is so great that interest, storage, depreciation, and obsolescence charges unduly increase unit costs; if the quantity purchased is so small that the unit cost of procurement is disproportionate, or so large that interest and storage charges increase unit costs unduly.

In the better-managed plants, accurate information regarding prices and price trends is being obtained regularly from records of previous quotations, reporting services, trade journals, manufacturer's associations, governmental and semi-governmental sources, daily papers, graphical price analyses maintained by the purchase office, and many others. This information is studied carefully and constantly. The quality of purchased materials is being insured through the use of properly prepared specifications in making the purchase contract and in inspecting the goods when delivered. To insure deliveries as promised, vendor's records, showing capacity and past performance of each vendor from whom the company has had occasion to buy, are studied before the order is placed. These and other precautions may be taken to insure that the company gets the right quality, delivery, and price. However, the determination of how much to buy may not receive the same careful treatment.

It may be left to the judgment of some individual who is thought to be competent, very often the president of the company. It may be based on maximum ordering quantities determined from statistics of past consumption, having little reference to future needs. It may be based on immediate needs as indicated by present unfilled orders. Any or all of these methods may result in the purchase of quantities too large or too small to give a minimum total unit cost.

### Relation Between the Receipt and Consumption of Purchased Materials

The general relation between the receipt and consumption of purchased materials is indicated in Fig. 1. The ideal condition would be an assured delivery of the exact quantity of material necessary to meet the needs of the plant, at the exact time that the old stock is exhausted, making it unnecessary to carry reserve stocks. Of course, such an ideal is unattainable in actual practice, although some concerns have approximated it to a surprising degree. Obviously, the trend in inventory practice is to approach this ideal as a limit, as far as practicable.

In Fig. 1, values of time are represented on the axis of abscissas and values of quantities purchased or in stock on the axis of ordinates. The symbols in the diagram have the following meanings:

$Q$ = quantity purchased, which should be such that the total unit cost is a minimum.

$R$ = minimum ordering quantity.

$R_1$ = theoretical minimum. If there is no reserve stock, and a purchase order is placed when the stock on hand falls to quantity $R_1$, the old stock will be completely exhausted as the new stock arrives.

$R_2$ = reserve stock. It is assumed that some reserve will always be maintained to protect the plant against the failure of the vendor or the carrier to deliver as specified. The size of the reserve depends on the time required for procurement and the nature of the article rather than on the size of the order.

$S$ = rate of consumption, expressed in pieces per year.

$T_1$ = procurement time, expressed in years. It includes the time from the origination of the purchase requisition to the delivery of the goods to stores. The procurement time will vary with kinds and classes of goods. However, for any given item

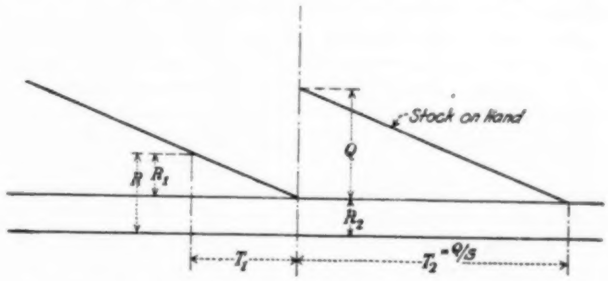

Fig. 1 Relation Between Receipt and Consumption of Purchased Goods

it does not vary greatly with the size of the order. It can be considered to be a constant.

$T_2$ = the time during which the stock is being consumed, expressed in years.

### The Minimum Ordering Quantity

In many plants, one source of authority for the placing of a purchase order is the purchase requisition originated by the balance-of-stores department. When the available stock of a given item, as shown on the stores ledger, falls to some predetermined quantity, a purchase requisition is originated and sent to the purchasing department. If it is not the practice to apportion material against planned orders, the quantity will refer to the stock on hand. This predetermined quantity is usually referred to as the minimum ordering point or quantity. Obviously, its value depends on the time required for procurement and the rate at which the item is being consumed. This being so, $R_1 = T_1S$.

The actual reserve will include the theoretical minimum plus the reserve necessary to protect the plant against exhaustion of stock before the arrival of the new stock. In general, the greater the time of procurement or the quantity consumed, the greater the reserve that must be carried. The probability of delivery failures or rejections due to failure to meet specifications tends to increase as these factors increase. The actual reserve can be

---

[1] General Motors Institute of Technology.

Presented at the National Meeting of the Management Division of The American Society of Mechanical Engineers, Rochester, N. Y., October 26–27, 1927.

expressed as a function of the theoretical minimum. Let $F$ = ratio of actual to the theoretical minimum ordering quantity. Then

$$\begin{aligned} R &= \text{actual minimum} \\ &= FR_1 = FT_1S = R_1 + R_2 \\ R_2 &= R - R_1 = FT_1S - T_1S = T_1S(F - 1) \end{aligned}$$

In the above equations $T_1$ is considered to be a constant.

### The Maximum Ordering Quantity

The quantity ordered also may be controlled by means of the balance-of-stores ledgers. In many cases a quantity, usually called the maximum ordering quantity, appears on the ledger sheet for each item carried in stock. This is a predetermined quantity intended to limit or specify the quantity which shall be ordered at any one time. If too little is ordered at any one time, the unit cost of procurement will be too great. The cost of procurement includes such items as the expense of originating the purchase requisition, the time of major executives spent in consummating the purchase, the time of buyers and clerks spent in investigating markets, securing bids, and placing purchase orders, time spent in following up the order, the expense of receiving and inspecting the goods, the expense of stowing, the expense of closing out purchase orders in the purchasing and accounting departments, and similar items. The determination of this value for a given item means considerable analysis. However, when once determined it stands as a standard cost until there is a considerable change in conditions.

As the quantity purchased at any one time increases, the unit cost of procurement decreases, but the unit interest and storage charges increase. The total unit cost of the item decreases up to the point where increasing unit interest and storage charges outweigh decreasing unit procurement charges. Beyond this point the total unit cost increases. Obviously, the maximum ordering quantity should be such that it will hold the total unit cost at this turning point.

The interest charge depends on the quantity purchased, the time of consumption, and the rate of interest. It may be determined as follows:

Let

$$\begin{aligned} W' &= \text{quantity on which interest is charged} \\ &= Q/2 + R_2 \\ &= Q/2 + T_1S(F - 1) \\ T_2 &= \text{time of consumption} = Q/S \\ I' &= \text{total interest charge} \\ I &= \text{current rate of interest, and} \\ C'' &= \text{unit purchase price.} \end{aligned}$$

Then

$$\begin{aligned} I' &= W' \times C'' \times I \times T_2 \\ &= [(Q/2) + T_1S(F - 1)]\,\frac{C''IQ}{S} \\ &= Q^2\,\frac{C''I}{2S} + QT_1(F - 1)C''I \end{aligned}$$

The storage charge depends on the unit storage space required, the cost of storage space, and the time of consumption. It may be determined as follows: Let

$P$ = unit storage charge. This includes the proportionate share of the general overhead charges as well as those which result from the operation of the stores department.

$B$ = bulk factor, expressed in square feet of net storage space required per unit of item. Storage space is valuable. Against it can be resolved many charges such as light, heat, taxes, ininsurance, wages, and salaries. The greater the quantity purchased, the greater the charge, offsetting somewhat any savings from quantity buying. The term "net floor space" means net usable floor space, exclusive of aisles, steel bin frames, etc.

$E$ = storage charge, expressed in dollars per square foot of net storage space per year. It is based on the expense of such items as were mentioned in connection with $B$.

Then

$$\begin{aligned} W &= \text{total quantity in stock on receipt of the purchase} \\ &= Q + R_2 \\ &= Q + T_1S(F - 1), \\ P &= BET_2 \\ &= BEQ/S, \text{ and} \\ PW &= \text{total storage charge} \\ &= BEQ/S[Q + T_1S(F - 1)] \end{aligned}$$

The minimum-cost quantity can be found by setting up an equation of total unit cost, differentiating with regard to quantity, and placing the first derivative equal to zero.

If $G$ represents the total procurement cost, the equation of total cost may be written

$$\begin{aligned} C &= \text{total cost of the order} \\ &= G + I + PW + C''Q \\ &= G + Q^2\,\frac{C''I}{2S} + QT_1(F - 1)C''I + Q^2\,\frac{BE}{S} + QT_1(F-1)BE + C''Q \\ &= G + Q^2\left[\frac{C''I}{2S} + \frac{BE}{S}\right] + QT_1(F-1)(C''I + BE) + C''Q \end{aligned}$$

To simplify the statement, let

$$\begin{aligned} K &= \text{interest factor} = \frac{C''I}{2S} \\ H &= \text{storage factor} = \frac{BE}{S}, \text{ and} \\ N &= \text{reserve-stock factor} = T_1(F-1)(C''I + BE) \end{aligned}$$

The total-cost equation can now be written as follows:

$$C = G + Q^2(K + H) + QN + C''Q$$

Dividing through by $Q$, it may be converted into an equation of total unit cost, as follows:

$$C' = \text{total unit cost} = G/Q + Q(K + H) + N + C''$$

Differentiating with regard to $Q$, we have

$$\frac{dC'}{dQ} = K + H - G/Q^2$$

Placing the first derivative equal to zero,

$$K + H = G/Q^2$$

$$Q^2 = \frac{G}{K + H}$$

$$Q = \pm\sqrt{\frac{G}{K + H}}$$

In as much as the negative sign has no practical significance, the equation for determining the minimum cost purchase quantity is

$$Q = \sqrt{\frac{G}{K + H}}$$

In using the equation, the values for $B$, $E$, and $G$ would be determined by investigation. But once determined, they would be standard values until there were some considerable changes in conditions affecting them. The value of $S$ would be derived either directly or indirectly from the production program. The value of $C''$ would be obtained from the accepted bid.

The equation is not intended to take the place of executive

judgment but rather to supplement it. The executive's decision may be affected by considerations of quality, delivery, price trends, obsolescence, and depreciation, as well as quantity and quoted prices. The following example will suggest possible applications of the equation.

*Example.* It has been determined from the production program that approximately 10,000 pieces of the material in question will be required during the coming six-months' period. The market price is $0.10 per piece. The outlook is for a stable market. The procurement time is approximately four weeks. The expense of procurement for this class of material is estimated at $10.00 per order. The material is stored in standard bins, 2 ft. square, having a cubical content of 8 cu. ft. There are four tiers in a bin stack. Approximately 100 pieces can be stowed in a bin. Normally a 5 per cent reserve stock is carried for this item. The cost of net storage space is estimated at $4.00 per square foot per year. The current rate of interest is 6 per cent.

$$B = \frac{4}{100 \times 4} = 0.01$$

$$S = 20{,}000 \text{ pieces per year}$$

$$H = BE/S = (0.01 \times 4.00)/20{,}000 = 0.000002$$

$$K = C'I/2S = (0.10 \times 0.06)/(2 \times 20{,}000) = 0.00000015$$

$$G = \$10.00$$

$$Q = \sqrt{\frac{G}{K + H}} = \sqrt{\frac{10.00}{0.00000015 + 0.000002}} = 2145 \text{ pieces.}$$

The minimum ordering point would be determined as follows,

$$F = 1.05$$

$$T_1 = 4 \text{ weeks or } 0.0833 \text{ year, approximately}$$

$$R = FT_1S = 1.05 \times 0.0833 \times 20{,}000 = 1749 \text{ pieces.}$$

In this case, it would be advisable to purchase on the market in lots of 2200 pieces. The balance-of-stores department would originate a purchase requisition when the available supply fell to 1750 pieces. Under this arrangement, each lot would cover approximately $5^1/_2$ weeks' requirements. Before placing an order for a particular lot, actual consumption could be checked against the original consumption estimates, based on the production program.

## Discussion

Alonzo Flack.[2] This paper is undoubtedly the result of considerable thought and care in its preparation. After studying it, no fault can be found with its mathematical accuracy. It would seem that the practical application of the formula to all kinds of purchasing is the question to be discussed.

Many classes of materials are purchased in any large or small plant:

*a* Some quite regularly in easily predetermined quantities;
*b* Some in easily predetermined quantities but at irregular or uncertain intervals;
*c* Some in large quantities, but only once every year or two;
*d* Some only on schedule, a stock never being carried; and
*e* Some, such as tools, equipment, and supplies, in varying quantities and times of delivery.

The author's formula will apply best to the condition first mentioned. A large automobile company that schedules its production six months ahead is a good example. Even such a company revises its schedules monthly, after checking its schedules of production with its sales. When a more complicated situation arises such as is indicated in the other conditions, trouble may be found in applying the formula.

A tremendous number of variables are encountered in purchasing that tax the ability of a purchasing agent. Seasonal demands, changes in style, changes in prices, changes in manufacturing and marketing methods, will affect the practical application of the formula.

There are thousands of purchasing agents, their assistants, and storekeepers. The abilities vary widely. Many are of limited education and training. Some are of great ability but have forgotten their mathematical teachings. Such would find an easier way to determine the quantities to purchase, even though not as accurate.

Frequently the character of the purchasing agent has a great influence on the determination of minimum-cost purchase quantities. It is his knowledge, his accurately kept records and statistics, and his influence over those whom he supervises and from whom he buys that stamp him a success. Mechanical and mathematical aids are but auxiliary to his ability.

It is therefore a question whether the average person handling stores and purchasing can intelligently apply the formula, and to what extent it might be used. To get an unbiased practical reaction to the paper, a very successful purchasing agent, one whom for eighteen years has purchased large quantities of materials, has secured unusually favorable prices, and has been known for having prompt deliveries, was approached. He expressed himself as follows:

> The paper is the result of very careful thought of a very scientific mind and is a finished piece of work theoretically. It may be applicable to a very large concern with widely scattered operations, but is very impractical to a company doing three million dollars' worth of business per year, whose purchasing department has been working under the same supervision successfully, including the war period, when 1200 people were given uninterrupted employment. Not one single employee lost five minutes' time for the want of material with which to work, neither was substitution of material necessary for this operation. Based on this paper the cost of purchases (at $10 per order) would be $7200, whereas the actual cost was $900 with a very much simpler method than that above, which has proved 100 per cent efficient for 18 years.

In the writer's 20 years of service to industry, he has not found it practical to reduce the determination of minimum-cost purchase quantities to a mathematical formula.

Robert T. Kent.[3] The criticism of the practical purchasing agent quoted by Mr. Flack illustrates a point of view that probably has done more to obstruct the advancement of good management methods than anything else. Mr. Henry L. Gantt, one of the keenest minds that this Society ever had, coined an epigram which fits very closely individuals of the type of this "practical" purchasing agent. The epigram is: "The way we have always done it is probably wrong."

There is nothing so obstructive to progress as satisfaction with the way we have always done it, and the man who says that he has been successful for 20 years and is satisfied, is a man who has closed his mind against any progress and any advancement. Where would industry be today if every one connected with it took that view? Progress is made because we are not satisfied, and we know that our present methods are not the last word. If anybody can show better methods we should be only too willing to adopt them and discard our present methods.

[2] The Emerson Engineers, New York, N. Y.

[3] General Manager, Bridgeport Brass Co., Bridgeport, Conn. Mem. A.S.M.E.

W. R. Clark.[4] Mr. Raymond has given us a paper covering a formula for manufacturing,[5] and the author has given us a formula for purchasing. There is a missing link between these papers somewhere. Both are based upon certain assumptions and have neglected other considerations which must be entered into to make them wholly applicable.

Mr. Raymond's paper has neglected the question of labor fluidity, which involves the cost of training and the payment for overtime where those factors enter into the economic lot sizes, based upon demands of the purchasing agent. In other words, you may have a certain economic lot size which it is desirable to put into manufacture, provided you have the manufacturing facilities to get out this lot size and meet the purchasing agent's demand for delivery. If these facilities are not available, the problem becomes one of carrying more labor, training it, organizing a night shift, or paying overtime on the day shift.

Another factor that complicates the problem is the investment in surplus machinery, power, floor space, etc. in order to minimize the fluctuations in labor supply. Extra machinery may be installed in the plant, and extra labor can be temporarily put on this extra machinery in order to meet purchasing demands and permit economic-lot-size manufacture, but the cost of carrying this equipment is considerable. These are factors which should be covered somewhere in the equation. Another factor that enters into the problem is the variations of raw-material costs. At certain times, when raw-material prices are low, it may be advantageous to operate and put into stock an excess of goods over the economic lot size.

Referring to the author's paper, the condition of the vendor's factory may affect delivery. This condition varies from day to day, from week to week. Considerations must be given to the condition of markets, which affect the vendor's supply of raw material, and also the seasonal price variations of the raw material for the vendor.

Probably these variables can be tied together somewhat by a type of contract which is being made to a limited extent, that is, a procurement contract rather than a series of orders. It may call for a delivery somewhere between a maximum and minimum amount during a given period. Such a contract is somewhat flexible from the vendor's standpoint, where he can, to a certain extent, manufacture to his economic-lot formula and can put into his stores, temporarily, material in excess of specifications in order to enable him to meet the demands of his customers. The customer, in turn, may be able to work to a formula requiring less material in his storeroom.

The whole problem merits the getting together more closely of the purchasing agent and the source of supply from which he procures his material, in order that they may work out this problem as a whole instead of using two formulas not entirely connected.

The Author. The method of determining minimum-cost purchase quantities is not intended to be a substitute for the purchasing agent's experience and ability, but rather a supplement to it. Mr. Flack is correct in stating that such "mechanical and mathematical aids are but auxiliary to his (the purchasing agent's) ability." However, this does not preclude the possibility that such methods may render valuable assistance to the purchasing agent.

The method described in the paper is intended to aid in establishing maximum and minimum ordering quantities accurately. Obviously, it is of value only in connection with the solution of these problems for classified materials. It can be used for such materials purchased at regular or irregular periods of considerable duration or on schedule, as well as for those purchased in large quantities at relatively short regular intervals. However, the reliability of the formula is less in the former cases. Therefore more depends on the ability and experience of the purchasing agent. Nevertheless it is hardly probable that such ability and experience exercised by rule of thumb will be as effective as they will if they are supplemented by a scientific analysis of the problem, such as the proposed method will give.

Seasonal demands, changes in style, etc. would be considered in making the production program. Therefore they would be considered by the formula. In most cases the revision of the original program, as conditions develop through the year, would not affect the maximum and minimum ordering quantities seriously, unless the revisions were quite considerable. The properties of the curve of total unit purchase costs are such that there can be a considerable deviation from the minimum-cost quantity before total unit purchase costs increase seriously. The necessity for revising would vary with each item. In the case of the more important items which are used regularly in large quantities and whose purchases involve large sums of money, it might be advisable to revise the maximum and minimum ordering quantities whenever there is a general revision of the production program. The great majority of items would only be revised periodically.

The method is not intended for use with speculative purchasing. Impending increases or decreases in the price level of a given item are always a matter for the judgment of the purchasing agent, supported by such information as may be collected by his own or the company's statistical organization. It is always his privilege and responsibility to recommend such deviations from the maximum ordering quantity as he may consider advisable. However, it is doubtful whether he should be permitted to make such deviations at his own discretion, except in the case of those items whose purchase is frankly speculative.

There is undoubtedly the same wide variation in the abilities of purchasing agents that there is within any other executive class. Such variation is an argument for a more exact and careful selection and training of executive material rather than an argument against the use of more exact management methods. However, the work of determining maximum and minimum ordering quantities, in general, would not be done by the purchasing department. The actual solution of the problem for any given item is a routine matter, once the proper information has been supplied.

As previously stated, the formula is not intended to give exact solutions on which blind reliance can be placed. A number of factors in the purchase problem have purposely been left out because they are too intangible and their inclusion would unnecessarily complicate its solution. The formula is intended to assist the purchasing agent in making a more exact analysis of a given purchase problem in so far as the factors considered by the formula are concerned.

# Control of Quality

## Conditions and Circumstances Affecting Control of Quality Obtaining in the Shops of a Large Manufacturer of Optical Instruments and Accessories

By WALTER W. GRAEPER,[1] ROCHESTER, N. Y.

THE problem of the control of quality and its relation to production, in its general aspect, is the same in all manufacturing plants. The psychology of inspection, its necessity and value in securing a uniformity of product, is universally understood and recognized. It is doubtful if there may be found anywhere a factory in which some form of inspection is not applied. There may be instances in which it is carried out more or less unconsciously or in such a manner that it is not recognized as a separate function.

### Growth of Need for Inspection

The need for inspection has grown and developed with the change and growth of modern industry. When production and distribution of goods was operated on an individualistic basis, when the artisan worked as an individual, either at his home or in his shop, alone or with the aid of a helper or apprentice, inspection, as we know it today, had no place in the scheme. Yet standards of quality, as far as the finished product was concerned, were scrupulously maintained. This product was in most instances due entirely to the labor and skill of the individual working with his own tools. But with the development of the simple tool into a variety of complex pieces of power-driven machinery, specialized for the mass production of parts of commodities, the little workshop grew into an enormous factory in which hundreds and thousands of men and women were gathered together, organized into an elaborate system of labor, each working into the hands of the other, all of them collectively producing one article which frequently passed through numerous other operations and processes before it was turned into a commodity ready for distribution and use. Under these conditions, with the individual almost completely submerged, with the pressure arising from competition and the necessity for producing articles of high quality but at low cost, inspection, following processes and operations, of component parts, and, finally, of the finished product has become to a greater and greater extent a balance wheel which prevents these huge organizations from driving to ruin. The effect of a lapse of quality from established standards on sales volume, prestige, and good will is too well known to merit discussion.

### Value of Proper Inspection Generally Recognized

The value of proper inspection is universally recognized, but the methods of its application vary greatly. Probably the highest development of inspection methods is to be found in those plants devoted to the manufacture, in large quantity, in a more or less constant stream, of some highly standardized product such as the automobile. Beginning with the raw material, running through a bewildering number of operations, and ending with the completely assembled and finished machine, every step has been safeguarded by means of inspection. This is necessary because the ability of the machine to function, its utility, its length of life, and, in fact, under modern methods, its very existence depend on how closely to established standards its parts have been fashioned. Present production methods are such that a close check must be kept on the work in progress. Division of labor has resulted in economies which cannot be abandoned but it has also reduced the individual to an automaton so that, to a great extent, his incentive toward a striving for quality and his pride in his work have been lost. Barriers in the form of inspection must be erected to keep the quality of the results of his labor up to a standard which may be found acceptable.

Before going into a discussion of the problem of the control of quality as it presents itself at the plant of the Bausch and Lomb Optical Company, it may be well to refer briefly to the conditions and circumstances which obtain.

### Conditions and Circumstances Obtaining in Optical-Instrument Manufacture

This company is engaged in the manufacture of optical instruments of almost every description, together with an allied line of accessories not all of which may be classed as optical; of a large variety of articles made of glass, such as mirrors, reflectors, lenses, and prisms; of ophthalmic lenses and spectacle frames and mounts; of lens-grinding and polishing machinery. It is difficult to convey an idea of the complexity of these products by merely enumerating them. Optical instruments alone embrace so varied an assortment that it is possible only to those in the industry to become familiar with even a small percentage of them. The manufacturing problems which confront this organization are complicated by the fact that, gaged by the production of standardized articles manufactured in many other factories, the quantities involved are small. In the optical-instrument line alone there are roughly three thousand sales units according to the latest count. In the case of the most popular model of microscope the yearly production does not greatly exceed five thousand. For a great many units five hundred is considered big production, while others are made in lots of twelve to one hundred. In ophthalmic lenses and spectacle mounts and frames the quantities involved run into huge numbers, but the almost infinite variety of possible combinations of lens curves, types and shapes, colors and shades, and, in the case of frames and mounts the same conditions with respect to styles, materials, and the variables in the matter of dimensions required to fit them to heterogeneous human heads, complicate the problem to such an extent that the value which lies in great quantities in production is practically nullified. It has been found desirable to make use of practically all standard types of inspection methods, and means are frequently employed which are peculiar to the optical industry.

Without going into detail, it may be pointed out that facilities are available for making laboratory tests of raw materials which are used. Sands and chemicals for making optical glass must be tested in order that the glass produced may have definite characteristics as to index of refraction, dispersion, color or freedom from color, transmission, and absorption. Failure to control these characteristics leads to failure in the performance of complicated optical systems such as microscope, telescope, and photographic objectives. Metals of various kinds, from the gold which is used for spectacle frames and mounts to the brasses and steels from which instruments and tools are made, are tested to insure against failure during manufacture and use.

Tool inspection follows the procedure commonly adopted for

[1] Bausch & Lomb Optical Company.

Presented at the National Meeting of the Management Division of The American Society of Mechanical Engineers, Rochester, N. Y., October 26 and 27, 1927.

checking the accuracy and fitness of tools which are used in manufacturing processes. This work is carried out by a department set up for that purpose.

### Checks, Tests, and Inspections

Checks, tests, and inspections all through the processes of manufacture are required to maintain quality at the desired level. The diversity of the product brings into use a great variety of devices, instruments, and tools. These range from the usual gages and measuring devices for comparing physical dimensions, to refractometers, photometers, and many specialized optical instruments for measuring optical constants, curves, and angles of prisms and lenses.

Instruments especially designed and built in the plant for definite test or adjustment purposes are utilized. As a rule these are of such a nature that they are adapted only for the particular purpose for which they were designed, but not infrequently they develop into devices which, by reason of their accuracy or ease and rapidity of use, are adaptable for similar types of work in other industries. The contour-measuring projector is a good example of instruments of this kind.

Such instruments may be unusual, but the manner and reason for their use conform with standard practice for test and inspection. No doubt other industries find the development of specialized tools and instruments equally invaluable.

Previous to final inspection of the finished product, the control of quality is in the hands of inspectors who are responsible to division superintendents and department foremen in charge of production. This arrangement is based on the theory that the responsibility for the quality of the finished product should be shouldered by those who make it.

However, a check on the manufacturing departments has been provided. The final or finished-instrument inspection department is charged with this duty. It functions as an independent organization, responsible to the management, which passes judgment on the product of the factory. It is expected to carry out the policy of the management, and with this policy as a basis it establishes standards of quality and is empowered to force adherence to them. It has no direct authority or jurisdiction over the various processes of manufacture, yet its influence extends back to them. The manner in which this influence makes itself felt will be discussed later.

Due to the nature of the product, sales in the instrument lines are frequently made directly to the ultimate user. For this reason it is found to be advisable to fill many orders in the assembly departments. Such orders accompanied by the goods are routed through the inspection department for final approval and test. Other articles of a standardized nature are held in designated stock rooms after passing through the inspection department. From these points they are sent to the shipping department as orders are received. Since the inspection department is held responsible for the condition of the product as it leaves the factory, it has the authority to determine what articles may be handled in this manner and to restrict the length of time they may be held in stock without reinspection.

### Work of Inspection Department Not Entirely Non-Productive

The work of the inspection department is not entirely nonproductive. There are, for instance, instruments which are finally adjusted as they are being inspected and tested. On certain types of instruments some assembly work is done. This is confined to those which would have to be taken apart for the purpose of inspection if they were received in a fully assembled condition. The guiding policy in this connection is to do such assembly operations which do not add materially to the inspection time, but which result in a saving of a certain amount of time for the assembly departments.

The routing of equipments and combinations of equipments as ordered by the customer through the inspection department is advisable in order that they may be set up and put through a practical test in much the same manner in which they will be set up and used later by the purchaser. Because of the variety of units which are offered for sale, from which the purchaser may choose for his own requirements, it is not practicable to attempt to carry such equipments or combinations of units in stock for immediate delivery. This is also true of orders calling for special instruments and parts or modifications of instruments regularly supplied.

As has been stated, the tests are of a practical nature. Therefore inspectors who have been trained in the use of a large variety of instruments are required for that purpose. In general, instruments of a given kind or type are assigned to the various inspection groups. As a result, inspectors become specialists in these lines. For example, photographic and projection lenses are handled by one group, projection and photomicrographic apparatus by another. A third is responsible for a variety of units which are produced in relatively small volume. Among these may be mentioned microtomes and accessories, field glasses and telescopes, botanical apparatus, blood-cell counting apparatus, centrifuges, colorimeters, magnifiers, and microscope accessories. Optical measuring instruments, microscopes, and ophthalmic instruments are inspected and tested by individual inspectors. There is considerable overlapping among these groups and individuals, and to some extent it has been found possible to train certain inspectors along more than one line to take care of fluctuations in the volume of business and to provide for emergencies in the way of absences. It may be of interest to interpolate here that the labor turnover is practically negligible.

### Spot Inspection as Check on 100 Per Cent Inspection

In attempting to control the quality of such articles as ophthalmic lenses, lens frames, and mountings, and spectacle cases, the method of random or spot inspection is resorted to as a check on the 100 per cent inspection which is made in the various manufacturing departments. The purpose is to obtain the facts relating to the quality of the product for the management and at the same time to bring them to the attention of the manufacturing departments for their guidance. Since the 100 per cent inspection is carried on by operators paid on a piece-work basis, a check on their work is imperative. Here again the inspection department has no direct authority over manufacturing processes. It may recommend, and the psychology on which the relationship between the manufacturing departments and the final inspection departments is based is such that, as a rule, its recommendations are carried out. The effectiveness of any recommendations is considerably enhanced if the inspection department has built up for itself a reputation for fairness and impartiality, if it states its case firmly, but at the same time moderately, preferring rather to understate than to exaggerate.

Optical instruments which are manufactured for the Army and Navy are subject to the approval of Government inspectors. A naval officer is stationed at the plant in the capacity of inspector. Close cooperation is therefore required in order to meet the exacting requirements of Government specifications. The final inspection department does not concern itself regularly with this product.

### Problem of Establishing Standards a Complicated One

With this rough outline of the conditions and circumstances which exist in mind, it will be admitted that the problem of

establishing standards—for it is the function of this department to establish standards—and maintaining them is a complicated one. The policy of the company must be interpreted in such a manner that it may be applied practically to working standards for the various things which are made. Specifications which have been worked out by the technical and engineering departments in the form of blueprints and drawings are available in the majority of cases. Otherwise samples are used, so that, as far as physical dimensions, materials, and finish are concerned, there is usually something definite by which inspection may be guided. In the matter of performance there is constantly need of taking recourse to more intangible standards, standards for whose interpretation judgment must be relied upon. In all optical instruments and appliances image quality, to take a concrete example, plays an important role. To a certain extent only can this be controlled by means of samples. In the final analysis this extremely important matter must be controlled through the judgment of an individual who has acquired through experience the ability to state when an image is of sufficiently good quality to pass the test for a particular instrument. There are optical instruments, especially measuring instruments, for which it is possible to lay down very definite specifications in the matter of performance. A refractometer, for instance, may be held within certain limits of accuracy which may be determined by measuring on it certain test objects whose indices of refraction have been measured by means more accurate than the instrument in question. Whenever judgment plays as an important a part as it does in connection with inspection of optical instruments, every precaution must be taken to make sure that such judgment is based on a practical, sane, and reasonable foundation.

Variations from fixed theoretical standards occur in manufacture even when the utmost precision is required and no matter how definite the standards which have been established or how closely the limits have been prescribed. When judgment enters, the degree of variation becomes all the greater. For this reason, when standards of quality have been established in terms of samples, it is of utmost importance that these standards be studied and reviewed from time to time in order that judgment may be restrained from wandering too far from the desired limits. It is probably generally recognized that the normal tendency of an inspector is to become more critical without intending to do so and believing with an honest conviction that no change in the quality of his judgment has taken place. This tendency should be taken into account in handling the inspection problem.

### Contending Forces Which Influence Inspectors

There are two contending forces which influence the inspector. The one comes from the outside in the form of complaints by consumers and from the sales organization, which normally is a booster for higher quality in order that it may meet and overcome sales resistance arising from this factor. The other comes from inside the factory walls and arises from the struggle to keep down costs. It is particularly strong when manufacturing difficulties arise, when rejections mean retarded delivery, scrapped parts, and heavy losses. The quality of the same or similar product made by the competition becomes a component of one or the other of these forces. The direction in which it is effective depends upon whether this quality is higher or lower than that of the product with which it is being compared. It is not possible to maintain so fine a balance as an equilibrium between these forces under any circumstances, and frequently compromise must be resorted to. The effect is similar to that of a pendulum which vibrates between two points, and it is the function of the inspection department to make sure that the amplitude of vibration is restricted to a minimum—that the pendulum does not swing too far in either direction.

Customers' complaints in a large measure determine the limit on the one hand. Even here judgment must be used, for there are always to be found individuals and dealers who are extremely free to express themselves, but who lack authority. There are those whose demands are such that near perfection is required to satisfy them. To base standards of quality on their desires would be ruinous and impracticable from a commercial standpoint. Manufacturing difficulties and sales resistance due to high costs are the chief determining factors which must be recognized to prevent the swing of the pendulum in the opposite direction. As it is the policy of the management to head the procession, careful watch must be kept on the quality of the goods manufactured by competitors.

One of the most potent devices for transmitting back to the manufacturing and assembly departments the more or less intangible standards of quality are the inspection reports. Such reports serve two purposes. They convey the decision of the inspector together with his reasons in definite form and, when they have been analyzed, they form a record which is of practical use when reordering a lot of the same article. Since it is a part of the routine that manufacturing authorizations must be approved by the various executives whose departments are involved, the opportunity is automatically presented to the inspection department to make criticism or to suggest changes in design or method of manufacture which experience with the preceding lot of instruments warrants.

Conferences at which are present representatives of the engineering, production, manufacturing, and inspection departments before starting work on an article, have genuine value in creating a proper understanding of the problem at hand and in preventing thereby future difficulties. They are equally effective in getting results when trouble has been encountered at some stage of manufacture.

### Inspection-Department Policies

It is the policy of the inspection department not only to pass or reject the articles which come to them, but to find, when possible, the reason for failure and the source of the trouble. This policy frequently results in real saving, especially of time, for, as a rule, the inspector is in a more favorable position to detect sources of trouble in connection with performance than the individual who makes the parts or assembles the instrument. It results, further, in a closer contact with the manufacturing departments and presents an opportunity for a type of cooperation conducive to a better understanding between workman and inspector. No one relishes the idea of having his work rejected, especially when earnings are affected, but when the reasons for such rejections are pointed out together with information which is helpful in preventing similar mistakes in the future, it has been found that the natural tendency toward resentment has been mitigated, and that the average individual will make an honest effort to improve the quality of his work. Valuable suggestions relating to design and methods of manufacture frequently result from investigations of the causes of trouble.

It is the policy of the inspection department to give information whenever possible, for no matter how carefully drawings have been made, or how completely limits have been assigned, there constantly arise questions which must be answered, and information which cannot be placed on blueprints must be gathered if the complete intentions of the design are to be carried out in the finished product.

The idea that rigid inspection and high cost go hand in hand still persists in many places. The very opposite should be true provided that the inspection is intelligently conducted with a complete knowledge of the conditions which affect the design, manufacture, and use of the commodity which is manufactured.

Inspection if properly conducted should result in economy. Troubles may be quickly detected and their sources eliminated if the facts uncovered by the inspection department are utilized by the manufacturing departments as well as by those responsible for design. The solution of the problem of maintaining standards of quality is hastened if inspection is looked upon as a real source of helpful information and a means toward progress, instead of being considered merely as a retarding factor in production.

The philosophy of inspection is comparatively simple. The fundamental principles involved are such that they may be considered almost axiomatic. Yet, contradictory as it may seem, successful control of quality by means of inspection is difficult of attainment because of the complexity of the problem. Nevertheless, when production is approached by the management with as much emphasis being placed on quality as on quantity, when the factory personnel appreciates the value to itself of inspection and its by-products and is willing to cooperate to the fullest extent, when the inspection department has the proper conception of its responsibility and receives the necessary support to maintain its morale, adequate control of quality is possible of attainment.

## Discussion

L. G. Cattermole.[2] The author shows that the Bausch & Lomb Optical Company has followed the procedure of many other large progressive organizations in having developed sound, practical inspection methods. In general it would seem that there has been a letting down in quality standards among manufacturers of the low- and medium-priced products. This perhaps, has been due to increasing demand by the management for increased sales and decreased costs, influenced by the present narrower margins of profit in industry. While increased competition has a tendency to lower prices, it often has a tendency also to lower quality. In other words, the proper control of quality is not always coordinated with production.

Fundamentally, division of labor necessitates inspection to maintain predetermined standards of quality which would otherwise be unknown or not fully understood by the workers. When properly applied, it places responsibility for defective workmanship or material where it properly belongs. Carried to its logical conclusion, it insists on the immediate rectification of conditions where the percentage of rejections or repairs is too high. Workers, as a rule, endeavor to keep their work up to the requisite standards, when these are known, fully understood, and when they can be practically attained.

The middle road must be chosen between standards which are too low (or no standards at all) and standards which are almost impossible of attainment. In general, the small company errs in the first instance, and the large organization in the second. Proper inspection is as essential to special work, each item of which in the most extreme cases becomes an individual creation, as in highly standardized products, manufactured by automatic machinery.

The writer is opposed to placing the control of inspection at any time in the hands of those directly responsible for production, as is apparently done at the Bausch and Lomb Optical Company. The reason for this position is that the inspector is under pressure from two opposing directions—the need for quantity and the need for quality. One of the most satisfactory arrangements other than a separate inspection department, which is not often found, is to place the inspection department directly under the supervision and authority of the engineering department. In as much as the engineering department is directly responsible for the setting of quality standards, it is up to this department to see that such standards are attained. Such an alignment may eliminate the necessity of inspecting the inspector's work. The engineers are also in a better position to assist in correcting conditions which prevent the attainment of inspection specifications. Seldom is the engineering department given sufficient authority, responsibility, and scope for its activity. Care must always be exercised that conflict is avoided between the production and inspection groups. The conference plan, outlined by the author, is helpful in avoiding discord.

There are so many methods of inspection that it is difficult to lay down a hard and fast law applicable to all conditions. The author states provisionally that rigid inspection and low costs go hand in hand. This is not entirely true, as the law of diminishing returns certainly becomes effective in inspection work to a noticeable degree. In the final analysis the results to be obtained must be set against the *lowest cost* method of obtaining them.

B. H. Waterbury.[3] Many of the inspection methods, methods of establishing standards, factors influencing inspection, and inspection policies cited by the author, have their equivalents in other manufacturing activities than the one which he has considered. In the refining of petroleum, for example, inspection may be said to be one of the most potent factors in the maintenance of quality. This inspection begins with the crudes and continues through each process step to the finished product, whether that be aviation motor oil, cable saturant, fully refined paraffine wax, motor fuel, or other product. The development of special inspection apparatus has been necessary in some cases, as for making vacuum assay distillation tests, for determining the sludging properties of transformer oils, and for determining the resistance to emulsification of turbine oils.

Departmental inspection during the intermediate processing as compared with total inspection activities probably has a greater importance in petroleum refining than in most other industries. Standardization of all inspection instruments and master checking of inspection results, therefore, require close, skilled attention. Many of the larger refining companies maintain control laboratories whose work is closely coordinated with that of the Bureau of Standards.

Quality standards for many refinery products are established by recognized specifications. In the preparation of specifications there is, in the petroleum industry as in others, the necessity for the establishment of a rational mean between the ideas of quality sometimes held by customers and sales organizations and the urgency for low refining costs. In other words, as the author has suggested, in a desire to reduce sales resistance, certain product qualities, as for example, color and specific gravity, are sometimes disproportionately emphasized at the expense of refining costs.

With the majority of refiners the cost of inspection is an appreciable part of the total manufacturing cost, but an indispensable one in that it reduces other costs by enabling close control of operations, and in that it serves to maintain uniformly high quality of output.

R. T. Kent.[4] The question of inspection, like all other questions which arise in manufacturing, depends entirely upon the conditions surrounding manufacture. No hard and fast rule can be laid down for the inspection of a diversified number of products. The inspection system must be adapted to the particular manufacturing problem in hand.

There is no more important function in manufacturing than

[2] Cooley & Marvin, Boston, Mass. Assoc-Mem. A.S.M.E.

[3] Superintendent, Eclipse Works, Atlantic Refining Co., Franklin, Pa. Mem. A.S.M.E.

[4] General Manager, Bridgeport Brass Co., Bridgeport, Conn. Mem. A.S.M.E.

inspection. Faulty inspection means that faulty goods are going out to customers, inspected there and then returned to the manufacturer, who then has the privilege of paying the freight both ways.

In the organization of the inspection department, it is quite true that the inspector should be in contact with the man who is in charge of production. It should be the inspector's privilege to stop the work at any time that he finds it is coming through wrong. However, there is a development whereby a partial inspection can, with advantage, be put into the hands of the production men.

In our organization we have had a very elaborate inspection department, with process inspection in each manufacturing department. The process inspectors were entirely independent of the foreman. We found, however, that the inspector often had insufficient technical knowledge to enable him to correct faults in manufacture as they developed. The gap between the discovery of faulty products and the correction of the fault was considerable, resulting either in a large amount of spoiled work or of high expense for reclamation.

After a number of trials to eliminate the trouble, we developed the system of putting the process inspection squarely up to the foreman. The system evolved was that each operation, where trouble could occur, was inspected, the foreman making the rounds of the various machines in his department, inspecting the work as it came off the machine. If it was all right, well and good; if not, he stopped the work then and there. He would then ascertain what the trouble was and take immediate steps to correct it. After each visit of the foreman to the particular machine, the container in which the work was being placed, as it came from the machine, was set aside and moved away from the machine, the workman starting to fill a new container. If the foreman discovered faulty work on his next visit, the container containing the product was emptied and the product inspected 100 per cent. In that way we eliminated most of the spoiled work.

We have by no means eliminated the final inspection. Most of the products, before being sent to the customer, are inspected 100 per cent, depending upon the circumstances or quality of product.

W. F. Bailey.[5] In the writer's organization inspection is divided into three groups, two of which are under the manufacturing division and one under the Works Committee which will be dealt with later. Under the manufacturing group are the foremen of the various departments, who must go over the work in the department six times a day and carefully check it. It is purely a matter of inspecting the parts, the worker using the gage at the machine as a check on the work. The main inspection is under the manufacturing division also. All of these inspectors are in one room. A very simple conveyor system runs from each department to the inspection room to facilitate inspection of all the work. The work is so arranged that ten times each day the inspected material from one inspector is rechecked by another person, without the knowledge of the first inspector. A check is made for quantity as well as quality.

In connection with the general inspection, one man continuously checks up on the product. He will gather up a number of parts, and test them to make sure the work is right. In so doing he goes over a complete cleaner once a week. We also make a complete check on one per cent of our assemblies in this same department. We take a cleaner off the floor once a day, and take it to the tool room where every part is carefully measured. In this general inspection we try to catch the product at that stage where we can repair the article without spoiling it.

In the case of the motor, the winding is tested as it comes from the winding department, being checked for "stretch of wire," "open ends," etc. For instance, if the wire is stretched five per cent in winding it is noticed in the speed of the motor and corrective measures are taken. Before the armature goes to the dip, it is tested twice for "open shorts" and "grounds." That is a double inspection, two men checking on each other, because at that point we can correct most of the work, while corrective measures are impossible after it comes from the dip and the oven.

An interesting inspection is that of the beater bar or agitator. This is checked for the length of the beater bar, and extension of the beater-bar ribs before they harden. This part must be extremely accurately made, and it is given a 100 per cent inspection both before and after hardening.

The final inspection of the product is carried out by a group of inspectors functioning out of the jurisdiction of the production department and to a group known as the Works Committee inspectors.

This final inspection tests for wattage, speed, vacuum, lift of rug, adjustment to rug, and all appearances.

This group also makes a most accurate check on all incoming purchased material to make sure that the material meets the company's specifications.

The Works Committee inspectors answer to a group consisting of representatives from engineering, production, inspection, sales, service, and management, and of whom the general manager is chairman.

Through the service department inspection is also carried to the field. For instance, samples of dirt from California, Texas, and New York may be desired, and these men will secure the dirt prevalent in these territories direct from the homes. It may be found that dirt taken from a New York State home functions in the cleaner, but that the dirt from Texas will give a lot of trouble. Samples of dirt are sent in from these various places at certain intervals so that it may be determined whether or not the cleaners handle them properly.

Rugs are also distributed throughout the factory, placing them in the various departments where there is considerable traffic. These rugs are previously cleaned thoroughly, and they are 100 per cent clean before they are turned over to the inspection department. All kinds of rugs are tested to make sure that there is no type of rug that cannot be handled.

The question of incentive for inspectors has been mentioned by one of the speakers. The company is considering starting in its inspection department an incentive along the lines of a standard time system. Under this plan the inspectors will not only get their day rate but a certain percentage of the saving which they make. However, if some defect is found passing the first inspection, the inspection department which has passed it will be penalized four times the cost of inspecting the job. There will be an extreme incentive to speed up, making this saving in cost, but the whole saving is likely to be wiped out if the inspectors are not careful.

E. G. Quin.[6] In one branch of the Bausch and Lomb factory we have developed a wage incentive system wherein both quality and quantity are linked together with the emphasis on quality. The work is sent to the factory inspection department on whose report the operators are paid, based both on the quantity good and the total quantity produced. This inspection is entirely separate from the final or check inspection to which Mr. Graeper referred, which is not under the factory's direction. In order that there may be no favoritism in this factory inspection, the work of the different operators is arbitrarily sent through as that of operators Nos. 1, 2, 3, etc. In this way the inspector does

[5] General Superintendent, The Hoover Co., North Canton, Ohio.

[6] Bausch & Lomb Optical Co., Rochester, N. Y.

not know whose work is being inspected. Our final inspectors in the factory are the highest paid operators and we endeavor to promote our best operators to the group which does this inspection.

I would like to present a point for discussion which has not been touched upon. We will assume that both supervision and operators share in the wage incentive. What percentage of the penalty for rejected work should be applied to supervision and what percentage should be applied to the operators? Should the entire penalty be applied to the operators, should the entire penalty be applied to the operators and an additional penalty applied to supervision or should the penalty be divided between the operators and the supervision and if so in what proportion?

L. P. Arduser.[7] Methods of inspection depend to a large extent on the organization of a plant, and the articles manufactured. Inspection is first encountered, as a rule, in the purchasing department, which buys in accordance with more or less rigid specifications. The raw or partly worked material is carefully inspected by the receiving department as to quantity, and by that department or a plant laboratory, as to quality. This is true whether the material purchased is pig iron or seed clover.

The inspection department is frequently independent of the production department, and under a separate superintendent. The only real cooperation is between the superintendents of production and inspection, and a few of their department heads at the most. Inspectors pass on material after each process, using spot (about 10 per cent) inspection on parts such as rubber buffers, bolts, drawn parts, etc., and 100 per cent inspection on more important parts. What are called component units, and also final assemblies, are subjected to 100 per cent inspection, for "working qualities."

Parts made by automatics are given a running inspection by the set-up men. Small parts in process, after each process, are usually moved into separate inspection rooms. Large parts, hard to move, are inspected in the particular department concerned. The inspector's O. K. is necessary before any parts can be moved into stock- or be used in assembly. This inspection might be spot, or 100 per cent, depending on the article or component part considered.

Many component parts are moved into stock, to remain there for six months or longer. The reason is simple. A battery of automatics in two days can frequently turn out enough of a desired part to last a year. It can be seen that running inspection by the set-up men, and a further inspection by the inspection department, is necessary and an economy if "passed" stock is to be drawn out as needed. To take a battery of automatics, or only one, off of one job, set it up again for a temporary job, take it down and set it up again for the first job, is exceedingly expensive. This does happen sometimes, but it is not always possible to predict what kind of an order a salesman will bring in, and emergencies must be met. Better correlation of sales and planning activities will frequently prevent such a procedure.

In a certain electrical manufacturing plant, the inspection department, although independent of the production department, is nevertheless represented at all daily meetings of foremen, and also of department heads. Current troubles and differences of opinion are usually settled at the time by the engineering and inspection departments. The same system of inspection has been used for some years, and seems to be functioning well. This plant manufactures a complicated product, in which some 4000 different parts are needed in quantities of from 500 to about 40,000 per year. The various inspections vary from sighting along a line, to delicate electrical inspections with post-office types of bridges.

[7] John Wiley & Sons, Inc., New York, N.Y. Assoc-Mem. A.S. M.E.

In another plant, a sash and door plant, very little formal inspecting is done. Stair treads fit, or they do not fit. Since stairways are made up almost entirely by the same artisans, working from drawings, they do their own inspecting. Stock sizes of sash and doors are always correct to within a certain percentage. The carpenter is expected to use his plane on the job to make windows and doors work freely. Jigs, and even gages, are used more frequently in the wood industry, since quantity production, and long-distance shipments to consumers are more the rule than was formerly the case. Great advances have been made by the industry since engineers have been employed more frequently.

In still another instance, a radio plant employing some 6000 operatives had a force of about 150 inspectors. Costs were running up and competition was keen. Inspection was made on 100 per cent of the output, for both component parts and assembled units. The inspection department was independent of the production department. Production was irregular, sales disappointing, and returns from customers entirely too frequent. In a reorganization, the inspection department was cut to about forty. The foremen are now responsible for the quality of component parts. Their inspection is subject to a spot inspection by the inspection department. Whenever a certain small percentage of "no-pass" parts is noted, the foreman in charge of the department making that part is told to check the matter, and stop production, if necessary, until matters are righted. A final inspection of assembled units, for "working qualities" is made by the inspection department. This inspection is 100 per cent and is subject to a spot reinspection by the head inspectors. The inspection department, of this plant, is now present at all planning meetings, and confers on all purchases, on the manufacture and design of the product, and the design of new tools. The inspection department has a voice in manufacturing, and in the determination of policy.

Some engineers insist that inspection shall be absolutely independent of production, and that this function, at least, must be kept separate from all other functions of manufacturing. This may be correct in some instances, but it is not correct in all. Competition and costs determine the matter, to a large extent. Some leaders in business and industry are beginning to think that we have functionalized too much, and that the foreman should again be a foreman—at least as much as is consistent with retaining the benefits of the division of labor, modern automatic machinery, and large-scale production and sales.

The writer regrets that he cannot name specific plants, or the "some leaders" in industry, but it can be seen that for one in his position, who obtains more or less confidential information—often without asking—it would be unethical to divulge any names. The instances cited, and more, have all come under the writer's observation, either as an employee, or a representative of the publishing house with which he is connected.

G. J. Hopkins.[8] The similarities of inspection methods of all materials are, as the author pointed out, of two kinds: first, laboratory methods determining the quality of the material, which would cover the dryness of wood and chemical and physical properties of cast iron, as well as the purity of optical glass; second, the special gage-and-fixture method of determining sizes within exact limits. The only difference in these methods as applied to rough and fine goods is the width of the limit or tolerance allowed, and a consequent variation of refinement of the tools applied as measures.

However, there is one thing which does differ radically as between coarse and fine products, or rather between articles of

[8] McCray Refrigerator Corporation, Kendallville, Ind. Mem. A.S.M.E.

ordinary utility and precision instruments. This difference is in the amount of judgment required on the part of the inspection department to make sure that the policy of the house is carried out to the letter in the product offered the public.

The author has called attention to the effect of lapses from quality on the sales resistance, and also the effect of an increase of quality on increasing the cost. It would seem that in the case of precision instruments, very exact specifications can be drawn, but when we come to less exact items such as are affected by the public taste—let us say in the finish of automobiles—or the length of the useful life of the article, the policy of the house must be more or less governed by the kind of market in which it expects to sell, and the competetive conditions of that market. The salesmen are the men that eventually come into contact with the proof of the quality of the goods. They bring back to the house the public's judgment in the shape of reports to the management. These may be in the form of enthusiastic boosts, or neutrally written on a form, telegraphic, or verbal and profane. The greatest question, and the one that becomes most important as competition becomes keener, is "What method can be utilized to translate this mass of variable and often conflicting information into sound judgment for the inspection department to apply to new goods in process?"

In the writer's experience covering both kicks and plaudits in regard to a variety of goods going into the hands of users who are in some cases farmers and some mechanics, and some into the hands of retail stores for resale, we have never discovered a substitute for personal first-hand information, obtained by sending the chief inspector out into the field to determine for himself how high the quality must be carried to be satisfactory, and how closely the article must be trimmed to stay within its price class.

In other words, the writer's most poignant experience with inspection, both good and bad, has borne upon the chief inspector's actual knowledge of the goods in the field. It would, therefore, seem that in a highly organized production plant, the inspector should be no less a personage (except perhaps in the matter of organization ability), than the man in charge of the manufacture.

W. L. WALKER.[9] The author points out the need of the inspection of products to insure the maintenance of standards adopted by the manufacturer. Naturally, the relative amount of inspection found necessary in the various industries will vary between wide limits. In raw materials the chemical composition may be the most important consideration, while in finished products technical accuracy, strength, beauty, etc., may all count to make up the required standards.

Every manufacturer desires to make the inspection problem as easy as possible and to avoid the inaccuracies of human judgment wherever practicable. In order to accomplish this, products are standardized as far as possible, and the manufacturing operations are performed as far as it may be economical on automatic or semi-automatic machinery, where the required limits of accuracy are determined by the machines and are out of control of the regular machine operators. With the great increase in productivity of factory operators who are paid according to some well-planned wage incentive system, it is essential that conditions for accurate work are made as nearly fool-proof as possible. This is not intended as an argument in favor of hourly or daily wages to operators, as contrasted to a wage incentive system. On the average, better work will be performed by operators who are paid for their production by some wage incentive system whereby their rewards are largely under their own control, than by operators who are paid hourly or daily wages for their time.

[9] Asst. Gen. Mgr., Washburn Co., Worcester, Mass. Mem. A.S.M.E.

The transition from the artisan who had the interest of his own artistic expression in the products of his work, to the present-day factory operator, who may have only one of the numerous operations to perform on a product about which he knows practically nothing, has lowered the appreciation and responsibility for accuracy in work. Therefore, inspection is necessary, and the aim of the management of any industry is to control inspection as far as is possible by mechanical devices. Inspection costs, if not watched carefully, will increase beyond the limits allowable in any reasonable manufacturing budget. It is, therefore, advisable to study the needs at frequent intervals to determine just how far it seems practical to go in inspection work. In the business discussed by the author, it appears logical that a highly developed system is essential. In most of the industries with which the writer has been associated, the majority of the products manufactured are utilitarian, requiring few, if any, technical specifications of accuracy. Where technical accuracy has been necessary, certain mechanical devices have been developed which reduce most of the inspection tests to a routine, or chemical tests have been made by accepted methods of chemical analysis.

The author states that, where possible, the inspection operation should be made productive, certain other operations being performed while the inspection is made. This has been the policy in many industries.

The author also states that the chief inspector is responsible only to the management, in order that he shall have a free hand in determining quality. This is always advisable. Also, the policy of the inspectors should be not only to determine what is wrong with an article, but to investigate sufficiently to ascertain, if possible, why the product has become defective and, where practicable, to cause such changes in conditions as to reduce to a minimum the liability for the same kind of errors in the future.

The last quarter of a century of productivity has shown what the machine age could do in supplying human wants. In order to supply the enormous demand at the prices necessary, constantly improved mechanical equipment has been invented. Perhaps the most important achievement has been the development of modern production methods, whereby the men and women in industry have been able and willing through increased reward to show what they could do to increase output. The result of this has been that the production per person is undoubtedly larger now than at any time in history.

It is natural that the emphasis on production in many lines (not all) should have a tendency to detract from the interest in the art of industry. In an attempt to find a way out of this "profitless prosperity," suffered, perhaps, by the majority of concerns in competitive industries today, some are turning their attention toward products which will not only be satisfactory from the standpoint of utility, but which also will help to awaken and satisfy the artistic temperament of the customers. The function of beauty, which has long been partially or wholly ignored in the design and manufacture of many articles, may become the most important problem of the designer and manufacturer. If this comes, as it probably will, there will be another problem of inspection with which the average manufacturer is not familiar. Such inspection undoubtedly will call for the services of men and women who have a natural sense of harmony and artistic expression as well as technical training in the particular industries where they are employed.

With the designing of artistic products, and their manufacture in quantities under modern production methods so that costs will be low enough for a wide distribution, the management of the future must of necessity understand the detailed processes of production, administration, and distribution in order to keep the proper balance. It is to be hoped that with the development

of art in industry, coupled with the necessity of adequate technical inspection, as well as inspection for beauty and design, the control of production may still insure sufficient output for each employee or machine-hour to insure high wages and low costs.

W. L. Coley.[10] In the manufacture of precision instruments, such as made by the writer's company, quality is the most important essential. The users demand 100 per cent perfection, and for that reason we have never attempted to introduce piecework in our manufacturing. Our inspection is under the jurisdiction of an inspection committee, consisting of one chief inspector, production superintendent, and a member of the engineering department. The shop superintendent is responsible for standards. The committee has functioned for three years, and its duty is to anticipate trouble and prevent it. Another device that we use is a regular complaint system, which brings into the plant the ideas of customers on an instrument. The complaints are made in the form of a report, which is handed to those in the factory who may be responsible. The complaints are analyzed and answered. This system has enabled us to uncover many things which might have caused considerable trouble.

C. J. Roberts.[11] The writer is interested in knowing how the rates for inspectors are set, how they compare with the rates for operators on the machines, and whether the rates are set in comparison with the machine piece rates or with other standards, such as hourly rates. The type of inspector particularly in mind is that one who does not have to be highly qualified, say one who has been transfered from a shop job to the inspector's job. For instance, on screw-machine parts, where there is considerable routine work in the inspection of that product, girls are largely used as inspectors. What is the author's system for fixing rates for such work?

The Author. In reviewing the discussion, it is found that some difference of opinion exists as to the extent to which responsibility for maintenance of standards of quality should be entrusted to production departments. There seem to be two general plans of inspection in use. Under the one, all inspection is carried on by a separate department which is usually independent of the production organization. Under the other plan, responsibility for quality to some degree, especially where parts and processes are concerned, is assumed by inspectors reporting to departmental foremen or division superintendents. In addition, inspections and tests of the finished product are made by a separate department whose head is responsible to the management or perhaps to the engineering department.

At the plant of the Bausch & Lomb Optical Co., the second of these two general methods is in use. Parts and process inspectors are responsible to department foremen. In most of the manufacturing divisions separate inspection departments have been set up. The heads of these departments are responsible to the division superintendents. They carry on an inspection of parts and processes and in some cases, of finished product, but whenever the finished product is involved, their work is subject to spot inspection and control of the final inspection department which is an independent organization responsible only to the management.

The theory behind this arrangement is that it is easier to obtain desired quality when its maintenance is as much the responsibility of the production departments as is that of cost and quantity. It should be remembered that the establishment of standards is not under consideration in this connection, but only the matter of carrying them out in the finished product. Let it be assumed that standards of quality have been established for the production departments. It now becomes their duty to put them into effect. However, the final inspection department is the controlling and guiding agency which has been instituted to enforce adherence to the standards which have been set up. This department, furthermore, makes all working tests, on a basis of a 100 per cent inspection where finished instruments are involved, as has been fully explained in the paper under discussion. Through this plan a double check on quality is obtained such that, if faulty or defective merchandise should happen to be sold, both the inspection department and the manufacturing departments may be held responsible under conditions where neither may pass the responsibility on to the other. Satisfactory results have been obtained through this plan.

It is quite likely, however, that other methods may be equally effective in maintaining desired standards of quality and that varying conditions existing in different manufacturing plants may make their adoption and use desirable.

In reply to a specific question, it may be stated that no general rule is applied in determining the wages of inspectors. This cannot be done because the variety of product which must be inspected calls for various degrees of skill and judgment on the part of inspectors. For much of the routine work female inspectors are employed. These are frequently chosen from operators in the manufacturing departments because of their experience with the work, their higher than average intelligence, and their ability to use judgment. Such transfers are considered as promotions with resultant higher wages. The more highly specialized inspectors engaged in instrument inspection, in most instances, have had previous experience in manufacturing departments as skilled workers. They have been chosen because of their aptitude, because they have a temperament which makes them suited to the work of inspection. Their compensation, consequently, is higher than that of the workers whose product is being inspected.

The validity of the statement that rigid inspection should result in low cost has been questioned on the assumption that the law of diminishing returns becomes effective. The writer's viewpoint in this connection is based on the supposition that the manufacture of a given article is undertaken after definite standards of quality have been established and that these standards have been maintained in the finished product. It is reasonable to suppose that minimum costs may be brought about under these conditions through rigid inspection and its by-products. If, on the other hand, standards of quality have not been set up at the beginning of manufacture, it is equally true that lower costs will result if no inspection is instituted, but at the sacrifice of quality.

[11] Chief Insp., Leeds & Northrup Co., Philadelphia, Pa.

# Coordinating Wage Incentives and Production Control

## An Outline of the Principal Features of the Bedaux System

By OSCAR GROTHE,[1] CLEVELAND, OHIO

THE White Sewing Machine Corporation owns and operates the White Sewing Machine Company, the Domestic Sewing Machine Company, and the Theodor Kundtz Company. The metal parts of the sewing machines are built from the ground up, with the exception of the foundry work. The cabinets, or woodwork parts, are built completely, including the manufacture of veneers and panels and from rough lumber on. The school work, opera chairs, and auditorium seating are built complete, with the exception of foundry work. The church work, including pews, altars, and all the other furniture, is a straight jobbing business and built from the ground up. The various articles are marketed through different kinds of channels, that is, through the corporation's branch offices throughout the country, through dealers and jobbers.

The Bedaux plan is used in the operation of the manufacturing division.

In order that all may think and talk alike, as nearly as possible, in the organization, we combine together as production control (which is responsible as to where, when, and how many from the time of the inception of their requirements until leaving the factory) the following departments:

| | |
|---|---|
| Planning | Cost |
| Scheduling | Purchasing |
| Dispatching | Receiving |
| Timekeeping | Supplies, raw material and finished parts stock rooms |
| Payroll | |

Every one in industry is attempting, with varying degrees of success, to balance capacity with requirements, to establish and maintain control of raw, in-process, and finished materials, as well as labor and overhead, by means of some kind of plan involving scheduling, dispatching, etc. It should only be logical, whereever possible, to use all the records or measuring devices which may have been already established for other uses to accomplish this end, and thereby reduce the burden. For instance: Many companies make careful time studies of all operations, at quite an expense. In many cases they use this information for the payment of wages to the direct labor only, whereas this same information may, with slight additional work, be used for the payment of indirect labor, for cost records, budget, and other controls.

The foundation of our measuring stick or common denominator is a unit called the "B," which consists of a fraction of a minute of effort plus a fraction of a minute of compensating relaxation, always aggregating unity but varying in proportion according to the nature of the strain. In other words, it corresponds to the effort developed by a man working under normal conditions at a normal rate of effort for one minute of time. The average number of B units developed or produced per hour (or B-hour) is the measure of the labor rate of accomplishments, whether it considers the individual, the department, or the plant as a whole.

Generally speaking, and through the use of the B unit, control is established to give actual performance against standard expectations, and to analyze the differences. This enables those responsible to eliminate those differences which represent labor waste on such items as operators below standard, excess set-up, lost time, re-operations, and repairs or excess indirect labor. The control of production is attained through the application of standards, expressed in B's, to all forms of labor.

The B standard for any one operation represents the amount of labor, or energy, necessary to perform the operation correctly under existing conditions. It corresponds to the time in minutes necessary for a normal man, working under the existing conditions at a normal rate of speed and effort, to perform the operation correctly.

Planning of production simplifies itself to the relating of capacity to B requirements. Alterations to plans are treated in terms of the same unit, eliminating many of the burdensome details.

Instead of planning that machine No. 363 must on a certain day turn out operation 3 on 300 pieces of part 7, operation 1 on 450 pieces of part 210, operation 7 on 2500 pieces of part 16-A, and then figuring with all details at hand whether machine 363 has the physical capacity to do this, the planning department, knowing how many B's the machine is capable of absorbing in one day, assigns to it only as many B units as it can absorb. We have established, therefore, a measurement of human effort similar to the horsepower or watt.

In estimating bench-space requirements or capacity, again we use the same means of determining this as in the case of machine-hours, determining what the schedule requirement of B's may be and the capacity, also, for storage space. After having determined the requirements, B values are used for the purpose of determining how much storage is necessary to maintain the proper schedules, as the length of time required in process is definitely known. This is also true regarding containers of various types and kinds, of course always being careful to have them in convenient multiples whenever possible, for counting.

Dependent upon whatever the requirements of the particular institution may be, this information can be compiled for any individual machine, bench space, storage space, or container for any department, any particular type of article, or any kind of operation, group of parts, group of operations, or for the plant as a whole. It is a simple matter through this method to find out how many screw-machine B's of a certain kind are required, and again, how many are available, and so on, with drill presses and any other equipment.

For instance, in the cabinet-assembly department, where different combinations of styles are assembled on different days, and the units vary as to the amount of man power required for each, it is a simple matter to take the total schedule for any given time, whether one week, two weeks, or a month, and reduce this schedule to its B content by departments, and (or) by kinds of work, whether sanding, assembling, finishing, etc.; and then to take this total B requirement of any kind and reduce it to the daily schedule, and, in turn, each day compare the actual production with that schedule.

It would, of course, be impossible just to have a record of pieces as the department may be working one week on parts which require a small amount of labor, and the following week be

[1] Vice-President, White Sewing Machine Corp.

Presented at the National Meeting of the A.S.M.E. Management Division, Rochester, N. Y., October 26 and 27, 1927.

working on some parts requiring double the amount of labor. The second week they might find themselves behind in schedule, whereas they may have thought they were overmanned. We have, in the past, had foremen come to us, some to say they were overmanned, and some undermanned just because their list of parts or operations on their schedule appeared to be either caught up or behind; but now we can definitely tell by the B schedule and B's produced just what is required and we do not carry an excess of help in the various departments, as the man power required is figured down to the minute.

The problem of containers or shelving is handled in much the same way. Before we invest in additional equipment or dispose of some of the capacity available, we check the requirements, using B values of capacity and requirements as one of the measuring devices. Machine capacity, as previously mentioned, is also handled in about the same way, and we very frequently find that by changing the routing, or moving a machine, or sometimes both, a material saving can be effected. We are able to tell this by the B capacity rather than by machine-hours. At the same time, we know whether or not we are getting the returns from our investment and equipment by our B-hour record, that is, by a comparison of how many B's per hour are produced with what should have been produced.

This same B unit is also used for cost records. To obtain standard costs the base or hourly rates on a given operation, group of operations, or department, are divided by 60 (as there are 60 B's per hour in a standard performance). This, then, would give the standard cost per B. Then the B's produced divided into the money spent for direct labor gives the actual direct cost. The B's produced, divided into the indirect labor gives the actual indirect labor cost. The B's produced can also be divided into the other overhead items, separately or as a group, as the particular industry or company may require.

In the case of re-operations or repairs, as well as scrap, we again determine the B cost on the items for comparative purposes of one period for various departments against another. This gives a good barometer as to whether progress is being made or not. In the case of supplies, such as sandpaper, drills, and other items, it is easy to equate the use of these supplies against the B's produced on the various operations. In some cases we pay incentives for the savings of these supplies.

It is also a comparatively simple matter to make ratios of indirect time to direct B's produced, taking into consideration supervision, sweeping, trucking, and practically all other factors of indirect work for a given department. This same applies to set-up time, all measured in relation to production. The greater part of the information is figured each day for payroll purposes, which is essential for a proper labor control. One of the features of the entire plan is that with just a little additional work the various items mentioned, and many more, can be measured, and the entire organization is educated to think and talk in the same terms or language. This makes it easily possible to shift help from one department to another, to combine the work of various departments and reduce the force to a minimum, and to know whether the minimum is being reached.

The combination of these various data then makes it possible intelligently to plan, schedule, and dispatch the labor, material, and equipment as to where, when, and how many; and makes available most of the information necessary intelligently to budget and quite accurately to predetermine costs.

If, without compelling undue mental effort or complicated calculations, supervisors can be given the means to know exactly what is being done, compared with what can be done, and to know the true measure of usefulness of their men and equipment, the real value of their gains and of losses, the true measure of themselves in comparison with other men of its class, these supervisors may be counted upon to work with all their strength toward any improvement of conditions that will increase the measure of usefulness of their men and of themselves.

Give to industry the use of a common term, a constant unit of measure that places a true value on all work done, on all men employed—labor or supervision—giving the exact extent of all gains, losses, and errors, controlling all changes in schedules and processes, all expressed in a manner easily understood, and permitting, through its simplicity, a continuous grasp of the entire picture, and you will automatically transform useless efforts into useful ones.

## Discussion

H. O. Stewart.[2] Of exceptional interest is the recognition given to indirect labor in this paper, which brings out the point that indirect labor has an important part in assisting production. However, numerous workingmen in various plants, using the system described by the author, cannot see the justice of having deducted from their earnings a portion of what they earn on their increased production for the purpose of paying indirect labor. They feel that it is unfair, and of course that in turn is reflected in the quality of the product. In one plant the number of units requiring "reprocessing" increased from 10 per cent to 40 per cent after this system had been installed, and the foremen seemed to see very little hope of decreasing the amount of imperfections.

Why should not the indirect labor incentive be paid from the saving in overhead instead of somewhat at the expense of direct labor, inasmuch as the overhead is reduced whenever the production is increased?

C. C. Shipman.[3] When the organization with which the writer is connected installed the Bedaux System, a direct departure was made from former Bedaux installations in that the premium paid to the indirect labor as an incentive was paid by the company and had no influence whatever upon the wages paid the direct labor. The amount of premium paid was based on premium B's developed in the department and was a percentage of the base-rate earnings.

At the time "Bedaux" was installed, premium was only paid as an incentive for labor effectiveness; later it was found desirable to influence this premium by accomplishments on control of waste, machine maintenance, small tools, and supplies, quality of product, and cement and oils. Operating budgets were set on these various functions and the progress collected with the labor on the "Bedaux" analysis sheets, showing labor effectiveness and labor effectiveness modified by expense items. Premium is now paid on a modified application.

The standards set are workable, are competitive between departments, and have changed the viewpoint of our foremen to that of managers. The scheme is psychological, and has created interest which has resulted in the development of the operating personnel.

During the first year in which this system was used the above items were reduced to an appreciable level, resulting in savings to the company many times the cost of the premium paid.

Martin Keller.[4] The laborer after all is the important factor in the cost and production of a product. He is a human factor. The writer's idea is that if we have a superman who can earn 50 per cent more than the average, he should get his 50 per

cent increase. In this way he has a very definite incentive upon which to put forth his efforts.

Under incentive plans, the Bedaux system, etc., the employer does not pay all employees what they earn above a certain average. Some of it goes to the overhead workers, or management. It would seem an injustice to the superman to have part of his earnings taken away from him. It destroys the incentive to become a superman.

The writer cannot picture obtaining the maximum production from the men by means of the Bedaux system when the men do not receive all of their earnings.

It would seem that the morale of the whole organization would be affected when the men are not paid all of their earnings. Or to put it another way: on the piece-work basis they are earning a certain amount of money, depending on their speed and ability, and if another system like the Bedaux is installed, by which they will not receive as much, how can the faith and the confidence of the organization be kept?

W. R. McCanne.[5] When the Stromberg-Carlson Company began the installation of the Bedaux system in 1921, there was no desire to reduce wages. On the contrary, it was desired to keep the earnings where they were and at the same time increase production, so as to lower costs. The plant operated partly on day work and partly on piece work, and not more than 50 per cent of the current production was covered by piece-work rates. Under those piece-work rates the employee was being paid for a full 100 per cent of the actual production.

The Bedaux Company's recommendation was adopted that a standard task be assigned on every operation, and in excess of that standard task, 75 per cent of the value of the production should go to the productive worker. The balance of the extra production should go to the foreman, assistant foreman, supervisors, machine and maintenance men, machine set-up men, truckers, and those who assist in providing the right conditions for increased production. Many workers were changed from the 100 per cent plan to a 75 per cent plan, and in about 90 per cent of the cases the employee's earnings increased.

To cite a particular instance, two good men who had worked under piece rates on the assembly of telephone generators for years were called upon for an increased task. They said that it could not be done. After using various expedients, we finally enlarged the size of the tray which held the generators from a capacity of 25 to a capacity of 30, and we found that they performed the operations on the same number of trays they had done formerly. In that way we increased the production to the point desired.

In the final analysis these plans are just tools. Their success depends upon the application, the seriousness of purpose, the diligent follow-up that is put behind any one of these plans.

The Author. It appears from these discussions that their writers have somewhat strayed from the topic under discussion, that is, "Coordinating Wage Incentives and Production Control."

The discussion seems to be leading into the merits of the Bedaux plan of wage incentive for the operator; however, I shall be glad to give my version in connection with these discussions.

I have at no time said, nor believe, that we are not paying operators everything that they are earning; on the contrary, it is our intention and we do feel that we are paying the operators everything which they are actually earning. As Mr. McCanne explains in his discussion, practically all operators under this plan earn and receive more pay than under previous plans. The mere fact that the particular operator has produced more than in the past is not sufficient proof in itself that the operator had earned at the same ratio, inasmuch as there are others in the particular department that have assisted and helped in such a way to make it possible for this operator to turn out more work, and it was not necessarily by his own efforts alone. I am fully agreed, and always will be, that each individual shall receive all he earns, but I do not feel that there is a constant ratio between earnings and production at all times.

Referring to Mr. Stewart's discussion regarding quality: It has been the general experience with all types of incentive plans that the highest producers average the best grade of work, regardless of whether this be the Bedaux plan or any other, and it would be my opinion that there was something radically wrong with the management in the particular case which he cites where "reprocessing" had increased from 10 per cent to 40 per cent due to an incentive wage plan. Perhaps prior to that time it was a case of not having the proper records or measuring devices for bringing this waste to light, and in any case I should think it a sign of weakness to take the foreman's word alone as to the possibility of decreasing the amount of imperfections, as it is quite a human weakness to make it easy for oneself.

Mr. Shipman, I think, very plainly brings out the point that this particular system, that is, the Bedaux plan, has very materially reduced the waste in his institution and made a considerable saving in cost. However, no plan alone will do any of these things—it requires good management with any plan; and as Mr. McCanne states, the plan is simply the tool or measuring device for management to use to accomplish its purpose.

# Control of Factory Overhead

By H. G. Perkins,[1] Detroit, Mich.

*The control of factory overhead is almost synonymous with good management. The so-called uncontrollable items of overhead, as well as the controllable items, are amenable to downward adjustment from many different angles.*

*Tactful discipline of executives, the education of supervisors in cost of materials and service of their own departments, and study or research to determine better and cheaper materials and methods, are essential to expense control.*

*Expectancy of promotion, personal recognition and appreciation by the higher executives, assignment of added responsibilities, and payment of bonuses to executives, often greatly influence the esprit de corps of an organization.*

*Uniformity in output is a factor of greatest importance in the standardization of costs, and for this reason a rate of production not in accordance with current demand for the finished product is often advisable so that costs may be maintained at their proper levels.*

*A properly designed and vigorously administered budget-control scheme is a very powerful means of overhead control, and should cover such points as the attainability of quotas set, a voice in setting quotas by department heads, the provision of cost data for guidance of department heads, the establishment of well-defined standards of operation for various departments to act as checks on estimates and means of forecasting future performance, and the careful comparison of results with quotas in order to determine possible future economies.*

At first glance it would appear that the proper introduction to a discussion on the control of factory overhead should logically begin with the listing of all items of outlay charged to the overhead accounts, and proceed by a process of elimination to the selection of those items that may be classed as controllable, thereby eliminating from consideration such accounts as insurance, depreciation, and taxes, and give thought only to the so-called controllable group, including the well-known items of labor, material, supplies, and sundries.

Undoubtedly there is a widespread tendency to accept the uncontrollable elements of burden as necessary evils to which we must supinely resign ourselves. But before surrendering without a struggle, nothing will be lost if this viewpoint is challenged for the moment. Considering the element of depreciation, for instance, and assuming a flat monthly rate has been established on a most intelligent and scientific basis, has not management frequently taken the attitude that it has done well to set this rate at a figure assuring conservative and safe current cost, and at that point dismiss the matter by assuming that nothing else remains to be done? But is it not a fact that surprising possibilities for reduction of this charge are often revealed by closer study and more inquisitive analysis? Many institutions on a sound footing could discover hidden possibilities for reduction of depreciation charges if they had a more intelligent understanding of the extent to which these charges were influenced by the character of their maintenance and repair work, by the quality of their equipment and tooling, and by the diligence displayed in following the old axiom that a stitch in time saves nine.

Similarly, with insurance, is the significance of strict safety regulations, adequate plant protection, and elimination of hazards fully appreciated so far as their influence on insurance rates and amounts is concerned?

Perhaps this aspect of the question of overhead control can be disposed of with the statement that management errs if it accepts the term "fixed charges" too literally, and is guilty of negligence if it does not make an exhaustive analysis of every condition that influences this fixed-charge class of accounts.

### Weapons Available for Controlling Expenditures

When consideration is given to the controllable group of overhead accounts, it would seem that a proper approach will be made by listing the several weapons available for controlling expenditures. Without attempting to classify or name them in the order of their importance, these weapons will be given some brief comment.

*Discipline* undoubtedly takes a place somewhere in the picture. It is not difficult to conceive the disastrous results which must follow in an organization that does not feel the weight of the management's displeasure when excessive or unwarranted expenditures have been made. The moral effect of discipline must not be discounted. It might be said that discipline is of a negative value because it employs punishment for past shortcomings; but its influence on future actions is not to be underestimated. The spanked child does not immediately repeat an offense. So we may say that discipline is entitled to some measure of consideration in the control of overhead.

*Education.* Another weapon of somewhat different character, whose importance is often not fully appreciated, may be named by the term "education." Too often management has been inclined to exercise discipline, when as a matter of fact the fault lay at the management's door because responsibility given to an individual was not accompanied by instructions which would make that individual fully realize his duties or the possibilities within his grasp. It is an actual fact in the author's experience that a surprising number of shop foremen do not know the price of lubricating oil per gallon or the value of the perishable tools used in their departments. Management could do nothing more effective to control overhead than to educate its supervisory class to the proper interpretation of material things in terms of the dollar. The man who spends his company's money in actual purchase of incoming materials clearly visualizes the amount he obligates the company for. Is there less reason for a clear picture in the mind of the one who consumes those things? Educational work along this line is certainly an essential part of any well-rounded procedure on the control of overhead.

*Research.* A somewhat similar vein is the matter of research. Tireless study and investigation will often reveal possibilities of reduction of expenditure seemingly at an economic minimum. The author has seen many economies affected merely because of refusal to accept the current condition as being the last word, despite its apparent soundness. A persistent challenge of these apparently acceptable expenditures sometimes reveals surprising results in the way of substitution or elimination. As a case in point, the author knows of an instance where the substitution of crepe paper for cloth used to protect automobile interiors during assembly has resulted in a saving amounting to thousands of dollars. The surprising thing is that the experiment was not thought of years before its actual introduction. It may be stated as an uncontradicted fact that the control of overhead is incomplete if study and research are not in constant use.

[1] The Murray Corporation of America.

Contributed by the Management Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of The American Society of Mechanical Engineers.

*Incentives.* Another of the very important (if properly handled) means of reducing overhead is through the medium of well-regulated incentives to those responsible for results. One form of incentive which has come within the notice of all of us is the expectancy on the part of the executive of promotion in due time. When he accomplishes something a little out of the ordinary, or when he spends a considerable amount of excess time on the job—more than he is expected to do—or when by extra effort or unusual ingenuity he accomplishes an especially noteworthy result for the company, he is subconsciously thinking of promotion. This form of recognition is expected by all of us as we become more valuable to our employers through the acquiring of experience and knowledge of the particular work with which we are entrusted.

We have all seen the man of mediocre ability suddenly become transformed into a veritable dynamo of energy and endurance, solely because of a promotion, which though perhaps well deserved, was a little unexpected. It cannot be overlooked that the likelihood of promotion exerts a very great influence upon the will to accomplish and the desire to make a showing in some particular field. However, in order that promotion may be depended upon as a means of keeping executives on their toes, there should be a recognized procedure, a well-established and well-understood cycle of cause and effect, with cases in point from time to time judiciously brought to the attention of fellow-workers in a way that keeps them believing in the justice of the management with respect to this form of recognition for faithful and loyal service.

Another form of recognition which is seldom given credit for its real value as a means toward reducing manufacturing expense is the recognition of an employee by words of praise publicly given, or by suitable titles judiciously bestowed, or by giving an individual a certain responsibility which places him in the limelight among his fellow-workers and makes it a matter of pride for him to bring his individual accomplishment to the highest point. The author has seen many an indifferent worker suddenly take an amazing interest in company affairs by the simple means of a personal item in the shop newspaper. Even as simple a matter as being recognized in the shop by one of the higher executives has had this same effect, and a wish personally expressed by them many times produces results that could not be attained in any other way. Pride in this matter of recognition by those in the high places is indeed an important factor in causing employees—the executive no less than the worker—to take a keener personal interest in the economies and savings which are possible on his job.

*Bonuses to Executives.* Still another form of incentive which never fails to produce results when fairly and justly applied is a bonus to responsible executives. One outstanding criticism of bonuses of this kind, as they are operated in many cases, is the fact that the bonus has not necessarily been given to those most deserving of it. As it often has worked out, the individual who could put up the best appearance before his superior or who managed to get public recognition for some of his accomplishments, was the individual to receive the lion's share of any bonus money that was being distributed. An executive bonus, to be successful, must recognize ability and accomplishment only. That the individual be a personal friend or favorite of his superior, or that he succeed in advertising his accomplishments, must not be a prerequisite to receiving a bonus. The bonus plan must be worked out on an equitable basis, arranged to reward most those whose responsibilities for results have been greatest. Perhaps a brief description of an executive bonus plan designed to reward the individual executive in proportion to his accomplishments, as well as to foster a spirit of cooperation between department heads, would be in order at this point. The purpose of an executive bonus is, of course, to arouse keener interest in the financial success of the enterprise, and to induce each individual to do all in his power in his particular sphere of activity to increase profits. In as much as the amount of net profits is tangible evidence of the effectiveness of the endeavors of executives and supervisors, it follows that the net profits should be the basic element of the executive-bonus plan, and that the amount of the bonus shall bear some relation to the volume of net profits. Therefore, as a first consideration in the payment of an executive bonus, the profits available for a bonus after satisfying dividend requirements, proposed increases in fixed assets, required increases in working capital, and reserves for contingencies, must be ascertained. The plan in mind contemplates that in the event there are profits available for bonus, a base bonus of percentages of annual salaries varying with the individual's classification be paid for a range of net profits from the minimum at which it is considered proper for the company to pay bonus, up to a probable maximum. Having determined the base bonus rate for each of these classes of executives, it is arranged that adjustments will be made for individual performances. These adjustments will be modifications of the base bonus, either up or down, depending upon the performance of the individual in relation to certain fixed standards. The fixing of these standards is a comparatively simple procedure and will be outlined presently.

The first step in the determination of executive classifications is to divide the executives into a number of groups, classified according to their importance in the organization, or the responsibility with which each is charged. The percentages of bonus payable vary with the amount of profit and with the classification into which an executive falls. For any known amount of profits, the percentage of bonus for each class or group of executives has been established. This percentage, multiplied by the employee's salary, gives a base bonus, which is modified in accordance with the performance of the executive on the basis of the efficiency of the activities under his supervision. This includes three main items: namely, direct labor, the expense of indirect labor, and the use of maintenance materials and supplies. The figures measuring each one of these factors are readily available, as well as the standards for each one of these factors; that is, the amounts of moneys which should be expended in proportion to the production accomplished for each item. In the Chrysler Corporation these figures are obtained through the budget-control routine, and require no computation over and above that ordinarily made for budget determinations. Each of these factors in any given department is given a weight in relation to the other factors so that the totals in every case amount to 100. For instance, in a sheet-metal pressroom, direct labor might be given a weight of 60, productive labor a weight of 33, and supplies and maintenance expense a weight of 7, the total of these weights equaling 100. Then an efficiency rating for each factor is determined by dividing the standard or budget figures for each expense item by the actual expense for the period. The result is then multiplied by the weight of that factor, as just given, to get the adjusted weight for each factor, and the sum of these adjusted weights is the resulting overall efficiency of operation for the responsible executive. For example, it might be determined that direct-labor efficiency is 120 per cent of standard, that non-productive-labor efficiency is 90 per cent of standard, and that the use of supplies and maintenance showed an efficiency of use of 95 per cent of standard. We should then multiply each one of these efficiencies by its corresponding weight factor given above. In this case, the figures would be 72, 29.7, and 6.65, respectively, for the factors in question. The total of these figures, or 108.35 per cent, represents the executive's overall efficiency in the administration of his department. Next, let us assume for a certain amount of

net profit that the base amount of the executive's bonus would be 5 per cent of his salary. The actual bonus rate would then be determined by adjusting the base bonus rate of 5 per cent to correspond to an efficiency rating of 108.35 per cent, or by multiplication of these two figures. This resulting adjusted bonus rate multiplied by the executive's salary gives the amount in dollars and cents which the executive will receive as his yearly bonus. From this it is seen that the executive has something to do with the amount of bonus which he receives. By properly administering the affairs of his department, he increased the amount of bonus which he was expected to make, due to his position in the organization, by something over 8 per cent. It is needless to say that the amount paid the executive in bonus is quite negligible when compared to the savings effected, when reasonable intelligence is used in the application of the bonus. Staff executives, of course, whose duties do not involve either of the three adjusting factors of direct labor, indirect labor, or supplies and maintenance materials, are usually paid bonus at the base bonus rate for their particular class.

There are doubtless many other forms of incentives which can be applied to executives and those in responsible positions to accomplish the results of increased economy of operation. The three common incentives just discussed, namely, promotion, personal recognition, and bonus, are merely examples of the more prominent expedients that may be adopted to bring latent and dormant energy to the surface and convert it into company profits.

### Relation of Production Volume to Expense of Operation

It is becoming more and more the practice, especially in the automobile industry and other higher competitive manufacturing industries, to recognize the effect that ups and downs in production volume have on the expense of operation. It is of course well known that at times of curtailed output it is always advisable and sometimes necessary to retain a skeleton organization which at such times does not work at high efficiency. It is also common knowledge that as production increases, expense also increases, but at a slower rate, so that the unit expense costs at high-production are usually less than at low-production rates.

One of the methods used to show clearly the effect that variation of output has on various expense items, is to plot these expenses for past months against the production of the corresponding month. In almost every case the resulting graph shows very clearly the reduction of unit expense item costs with the increase in output of the plant. For example, the unit cost of operating the factory accounting department in one automobile plant was $24 per car when the output was 4000 cars per month; $19 per car with an output of 6000 cars; $15 per car with an output of 8000; $12 per car with an output of 10,000; $10 per car with an output of 12,000; and about $8.50 per car with an output of 14,000. Similar variations in unit expense costs are indicated for other non-productive departments, such as planning, stores, receiving, shipping, time study, machine repair, maintenance, etc. This reducing effect in the cost of overhead items with the increase in production is likewise apparent when the relation of non-productive men is considered for various rates of car production. In one plant the total non-productive men on the payroll per 1000 cars produced amounted to 425 with a monthly production of 2500 cars. When the production was 4000, the number of men per 1000 cars produced was reduced to about 300. Further increase in production to 6000 cars per month called for about 225 men per 1000 cars, and at 8000 cars production this figure was further reduced to 165 men per month.

### Stabilization of Output Throughout the Year

Not only in internal affairs, but also in those affecting vendors and distributors of product, the standardization of output plays an important factor. It might be well at this point to cite some of the means taken by a large automobile concern to stabilize output throughout the year. This is a matter of great importance to the automobile industry because of the big seasonal fluctuations in retail sales. These fluctuations are so pronounced as to be the outstanding influence on manufacturing costs. This problem is the most difficult and the most serious one the management of the automobile industry is confronted with. "Standard costs" is a term that has been honored with much consideration recently. The author will not be contradicted when he says that the greatest influence on standardization in costs is standardization of rate of output. The corporation mentioned fully appreciates the significance and importance of operating its shops on an even keel, and no production program is completely planned until the effect on costs has been estimated. This procedure has frequently resulted in a shop production rate either greater or less than the current rate of demand, especially in the production of individual parts or assemblies. They do not hesitate to increase the inventory of finished parts if by so doing a float or bank is created which at a later date obviates the necessity for operating at either peak or low demand. It might be said that the making of this decision is facilitated by the operation of a budget-control procedure that very accurately forecasts factory burden for every rate of production from minimum to maximum.

Efforts to standardize costs through standardization of rate of output should not stop with the planning of shop activities; since the fluctuation of factory output is controlled primarily by conditions in the retail field, dealer organizations may rightfully be asked to assume their equitable part in relieving the uncomfortable pressure borne by the factory during periods when the rate of output is over or under normal. The dealer naturally wishes to keep his stock of unsold products at a minimum in order to get the best turnover on his invested capital, but the dealer has a duty to the factory that sometimes necessitates carrying a stock in excess of current minimum requirements. The policy of operating a factory in strict conformity with the current retail demand not only affects the cost of output but the quality as well, and this is a matter of much concern to the dealer as well as to the manufacturer. Furthermore, if a manufacturer equips his factory for an output that will satisfy the peak demand of the dealer, he is confronted with the problem of idle machinery throughout the greater portion of the year. The only solution to this problem is to keep the rate of output from the factory as nearly uniform as possible and to take up some of this irregularity in dealer stocks.

The author would not give the impression that the company referred to is scheduling production so as to set up this uniform rate arbitrarily and then force this output upon the dealer. As a matter of fact, the rate of output does fluctuate reasonably with the field conditions. But this predetermination of ideal schedules opens the way for the factory to study retail-sales fluctuation more intelligently and to work out with the dealer a more satisfactory plan which to a large extent at least, will relieve the shop of much of the expense incident to changes from one extreme of production rate to another.

### Budgetary Control

One of the most active as well as one of the most powerful means of controlling expense is a properly designed and vigorously operated budget-control system. The comparatively recent interest in budgetary control as a specific tool of management has come about as a supplement to other developments and improvements in the science of management. Many refinements and improvements are yet to be made while it is settling into its

proper niche in the repertory of the modern industrial manager. It may be well to call attention at this point to the fact that mere installation of budgetary-control procedure will not in itself regulate expenditures. Budgetary control is simply a means to an end. It is a tool of the industrial manager's trade, and like other tools it must be designed for the work at hand in the light of past experience. It must be cared for and guided with a skilful hand if it is to serve the purpose of the master craftsman.

In the operation of budgetary-control procedure it is necessary that many contacts be made between the departments operating the budget and those in the organization responsible for actual results. Very much depends upon the nature of these contacts with respect to the results which may be expected from them. It is probably unnecessary to say that the relation of those operating the budget to those responsible for obtaining results in the factory should be that of the counselor, the guide, the helpful team mate. Dictatorial policies of the budget-control department are usually met with resentment, ridicule, and finally with contemptuous disregard. Cooperation can be realized best when those responsible for expenditures are allowed a voice in the determination of their budgets. Such cooperation usually results in budget quotas that are at once sufficiently reasonable to command respect and encourage thrift, and at the same time sufficiently rigid to stimulate vigilance on the part of the executive and prompt him to challenge every item of outlay with the words, "is this absolutely necessary?"

Like all attempts to discount the course of future trends, budgetary-control procedure and budget quotas should be based upon the experience of the past. Undoubtedly it should be the more immediate past, in order to avoid the mistakes which would undoubtedly occur in judgments based upon data compiled when manufacturing conditions were different.

As just mentioned, the mere setting of budget quotas does not in any way replace the necessity for strict, intelligent, and vigorous enforcement of means for the realization of these quotas in so far as is practically possible. Usually the type of man at the head of a department who would be called upon to submit proposed budget figures for his department would also be one from whom intelligent judgment on such matters might be rightfully expected. Furthermore, he is in a position to know the detail of the operation of his department, and therefore understands reasons which may not be apparent to the budget department for deviations from results which might seem in all fairness to be rightfully expected. It is the placing of attainable budget quotas before executives as guides in the operation of their departments and as measuring sticks for results which they are expected to accomplish that constitutes one of the biggest steps toward enforcement and accomplishment of budget quotas.

The next move is to provide the department head with sufficient detail data to enable him to actively and intensively study the situation in his department with the idea of enforcing the desired results upon his subordinates. Accurate reports and information showing the relation between actual accomplishments and budget quotas are essential in this respect. He must know how near he is coming to the mark in order to correct his aim the next time.

### Methods of Carrying Out Budget Procedure

At this point it might be well to describe briefly the methods used by The Chrysler Corporation in carrying out its budget procedure. This corporation was one of the earlier large establishments to adopt the budgetary-control method of operation. Of necessity its beginnings were crude, but as time has passed many refinements have been made in methods as well as in requirements imposed upon the budget scheme. Much that was thought necessary in the beginning has been cast aside as of doubtful value. Some other features not thought vital in the earlier days have later been developed and found extremely useful.

It is very natural for a department head, who is to be held responsible for results which he says he can accomplish, to make his estimates sufficiently high to enable him to avoid possible embarrassment if he should fail to meet his estimate. Furthermore, there is a tendency to set forth all kinds of excuses and alibis for not attaining his budget, claiming that he was not informed or that he had no responsibility in that direction, or that he was not consulted as to what the quota ought to be. When a department head is allowed a voice in setting his own quota reasonably close and is expected to attain that quota, he is much more likely to give the affairs of his department the close scrutiny which the preparation of an intelligent budget quota requires. It was found from the outset that it was necessary to establish some fairly well-defined standards of operation for the various departments in order that the accuracy of the department head's estimate could be measured intelligently. The first step in this direction is an exhaustive analysis of past performances. Statistics are compiled showing the relation between the volume of business and the volume of department outlays, and these figures are used as a basis for computation of a master budget, in which is set up for each department a standard expense per unit for production varying from the minimum to the possible maximum. The purpose of establishing these units of expense for each department is to act as a general guide in the preparation of budgets and as a basis for criticism when such budgets submitted were too far out of line. The master budget which resulted from this procedure was the management's idea of what a reasonably creditable performance should be. The aim was to make quotas such that they could be realized with good judgment and careful management without too great a difficulty, and to always have them backed up by similar performance in the past. When the department head understood that excessive budget requests above results which had already been attained required an explanation from him he was quite likely to give extreme care to the estimates which he prepared.

When final results for the month were available, they were compared with the quotas established, and any deviations which reacted unfavorably to the department were accounted for. The outcome of these explanations is usually a better understanding of the difficulties and requirements of the departments, and is usually reflected in more carefully set budget quotas for the ensuing months. In this way unnecessary expenditure is brought to light, and department heads are constantly kept alive to the necessity of reducing all avoidable losses to a minimum. By the continual process of forcing intimate investigation and analysis of the operation of his department, the department head is educated into the essentiality of expense reduction and prudent authorization of department expenditures.

While it is undoubtedly true that many businesses have prospered greatly which have never heard of "budgetary control," nevertheless, it is exceedingly doubtful that these concerns do not practice many of the principles laid down as fundamental to the operation of a budgetary-control feature. It is very likely that much of their success, much of their ability to reduce expenditures, to cut corners, to produce in the best, quickest, and easiest way, is directly traceable to principles which we are now talking and reading about under the name of "Budgetary Control."

## Discussion

F. Klein.[2] The writer's company has just completed a budgetary control of work expenses. While installing the system, we asked a foundry foreman to account for all of his indirect labor. We found he had incurred a number of charges of which he knew nothing. He was surprised to find that some men in the yard gang had been charging a whole day's time for about an hour when he had been using them. As a result of checking up on their time, the yard men soon had no place against which to charge their time, and a reduction of force was brought about.

Shortly after the budget was completed, a foreman had two carpenters come into a department to repair some flooring. The job was done in about one hour. The following week, the foreman was surprised to find that the maintenance account was considerably in excess of his allowance. Upon inquiry, he learned that the carpenters had charged six hours apiece for the job. He took the matter up with the maintenance superintendent and found that we had too many carpenters, who were simply inflating each account to take care of their idle time.

The foregoing are just little instances which occur in the installation of a budgetary control, and show that foremen do not know just what goes into the various accounts of indirect labor and other indirect items. As we go along with the regular weekly reports, we find other small leaks which will be eventually stopped through the continual control afforded with the budgetary expense control.

In setting up the control figure for each department, we first determine the 100 per cent operating capacity for that department. The number of different machines, or benches, or the other available space for productive labor is multiplied by the number of working hours in the week. The product is the 100 per cent capacity in working hours. A comparison with the number of productive hours which are actually being worked, gives the ratio of the present to the 100 per cent operating capacity. We then take up with the head of the department the requirement of indirect labor under his 100 per cent operating capacity, and step up the percentage of indirect labor to a possible 120 per cent or down to a possible 40 or 50 per cent, if those percentages are considered the maximum and minimum of the range of operations, and vary the indirect labor allowance according to the actual requirements under the various capacities. We also increase and decrease the supplies that are used in the products themselves, but proportionately. Those supplies which are used ordinarily in the maintenance of the department, supplies for cleaning, and those of a nature which do not increase or decrease proportionately, are set on a different basis.

[2] Worthington Pump & Machinery Corp., New York.

When the total cost of operation under different operating capacities is determined, it is entered on a chart which agrees with the set-up of the regular monthly report of indirect expenses. The top of the form shows the number of productive hours worked under each operating capacity. Under that is the percentage of operating capacity, and under that is the amount of money allowed for the different kinds of operating expenses. Thus when orders drop to a thousand from possibly 1500, we may call for a reduction of certain indirect men at that point. The tendency always is to keep indirect men in the shop in the hope that production will soon come back to normal, but when the budget shows that a reduction is in order but that it is not made, the foreman is required to account for his excess help, if the reduction is not made during the following week.

C. W. Spicer.[3] In our company we have carried budgeting and assignment of duties into the experimental laboratories and drafting room. No work is performed in those departments without an express order, approved by the proper executive. We have found that not so many drawings are asked for as formerly. In the experimental laboratories the work is budgeted so that only the necessary work is being done, and there are not so many individuals seeking information on particular details which may not directly relate to the work of the company.

G. R. Ingels.[4] The author states that the higher executive's premium or bonus should be based on the earnings of the company. The writer believes otherwise. Take any executive's position and list his duties. If he is on the production side, he has to do with the kind of material used and the amount of material used as limited by scrap factors and by labor. But in the total cost of an item being produced by most companies, the labor on it will seldom be more than 12 per cent. The cost of raw material is the big item. Most executives have relatively little to do with the cost of raw material—the biggest single item going into the cost of manufacture of a product.

Another item is the selling cost. Few executives have much to do with the earnings of the company. They have to do particularly with some one or two items rather than with a dozen items entering into cost. Should not those items be the ones to affect a man's premium to get him more interested, and should not the other items affect the other man's bonus likewise, rather than the earnings of the company? Prices may be set outside of the company, and the company may not have any earnings, yet there may be some man there doing wonderful work and deserving of a premium.

# Economic Production Quantities

## Derivation of Formulas for Determining Quantity Which Can Be Produced at Lowest Total Unit Cost, Taking into Account Fixed Charges, Investment Charges on Capital, Rental Charges, and Losses Due to Deterioration, Obsolescence, and Nature of Process

By FAIRFIELD E. RAYMOND,[1] BOSTON, MASS.

INDUSTRIAL executives and production managers are requiring more exact methods to enable them to control investment in inventories and to regulate production schedules so as to conform more closely with the variation of the business cycle, and to accomplish this with the most liquid condition of working capital. In most cases the greatest effort has been applied to reducing the unit cost of the product to the lowest possible in order to realize a satisfactory margin of profit under the conditions of aggressive competition evident today. Scientific methods of management have been developed in order to obtain all possible elimination of waste in time, labor, and material. However, no exact method has been established for determining the best quantity to be processed at any one time. The Economic Production Quantity is that quantity which can be produced at the lowest total unit cost, taking into consideration not only fixed charges on each process order, and investment charges on the capital involved, but also rental charges on the space occupied by the article when carried in stock, and losses due to deterioration and obsolescence and the nature of the process.

### Applications of the Economic Production Quantity

The law of the Economic Production Quantity provides a new and reliable means for directing and controlling the output of any industry by coordinating manufacturing and marketing conditions. Definite production schedules and sales policies can be properly established so as to anticipate the seasonal as well as the major swings of the business cycle. The planning department can be provided with actual facts expressed in the simplest form and based on the conditions of the manufacturing process involved, and schedules of work in process need no longer be maintained on estimates of an uncertain origin, generalizations, and the demands of insistent customers. Management can maintain a greater control of working capital, only tying up such amounts as the actual market conditions warrant, thereby maintaining inventories in the most liquid condition. Purchases can also be controlled by the formula for economic production quantities by the proper substitution of terms in the general equation, thereby correlating the receipt of raw material with the demands of the production schedules and eliminating unnecessary charges on capital tied up in such inventories.[2]

Moreover the type of process best suited to the manufacture of a given article, together with the probable machine capacity required, may be determined by this law. In general, processes can be classified according to the rate that production may proceed in order to balance consumption, and for further discussion will be considered as being either continuous, semi-continuous, non-continuous, or batch production. The last class modifies the third so as to realize the advantages of the first two which could not otherwise be accomplished. By means of a simple investigation of market conditions and an analysis of the sales demand the most seriously indeterminate factor of consumption can be reduced to a reliable and practical basis.

Although the ideal formula is complicated in appearance, it expresses the true relation of the fundamental facts, indicating the influence of each of these facts on the others, and establishes the economic law in a mathematical form. Mechanical means of solution such as slide rules, graphs and nomographic charts, can be developed, especially when the particular type of industry is known, which will shorten the time of calculating the economic production or purchase quantities.

### Mathematical Expressions

The law of the economic production quantity can be expressed mathematically in two forms, one exact and one approximate, and may be written as follows, showing the respective relation of the fundamental components:

$$Q = \frac{-F \times k'_s}{I''_s + I''_w + V''} + \sqrt{\left[\frac{F \times k'_s}{I''_s + I''_w + V''}\right]^2 + \frac{FPY''}{I'_s + I'_w + V'}} \quad \text{(Exact form)}$$

and

$$Q = \sqrt{\frac{F\,P\,Y'''}{I'_s + I'_w + V'}} \quad \text{(Approximate form)}$$

where

$Q$ = economic production quantity (pieces)
$F$ = fixed or preparation costs (dollars)
$P$ = rate of production (pieces per day)
$Y''$ & $Y'''$ = expressions representing the sales or demand (pieces per day)
$I'_s$ & $I''_s$ = expressions derived from $I_s$ representing the investment charge on inventories (dollars)
$I'_w$ & $I''_w$ = expressions derived from $I_w$ representing the investment charge on work in process (dollars)
$V'$ & $V''$ = expressions derived from $V$ representing the rental charge on the storage space (dollars)
$k'_s$ = coefficient representing the conditions involved in withdrawal of finished articles from stock to meet the sales demand.

It will be shown in the derivation of these various expressions that the other fundamental factors, such as variable sales demand, deterioration, and obsolescence are included in these final components as well as those factors which apply to the nature of the process or type of industry. These formulas for the Economic Production Quantity $Q$ are derived by differentiating the total unit cost $U$ with regard to $Q$ and equating the result to zero, as $Q$ must be by definition that quantity which is produced at a minimum unit cost. The total unit cost $U$ is composed of the direct production cost $c'$ of material, labor, and overhead, and the unit allotment of the preparation cost $F/Q$, the investment charges on inventory $I_s/Q$, and on work in process $I_w/Q$.

---

[1] Crosby Steam Gage & Valve Co., Assoc-Mem. A.S.M.E.

[2] The particular application of the law of the economic quantity to purchasing has been ably discussed by R. C. Davis in *Manufacturing Industries*, May, 1927.

Presented at the National Meeting, Rochester, N. Y., Oct. 26–27, 1927, of the Management Division of The American Society of Mechanical Engineers.

the rental charge for the storage space $V/Q$, and the loss involved by deterioration of articles in stock $D/Q$. This can be written mathematically as

$$U = c' + \frac{F}{Q} + \frac{I_s}{Q} + \frac{I_w}{Q} + \frac{V}{Q} + \frac{D}{Q}.$$

The exact solution requires that the cost of the finished article held in stock when applied to the expressions $I_s$ and $D$ be the total unit cost $U$, whereas the approximate solution assumes that the cost of the finished article in these two expressions is only the manufactured cost of such article when received in stock which amounts to $c' + (F/Q)$. In most cases when the law of the Economic Production Quantity is actually applied to a problem in an industry the approximate formula is used as it is sufficiently accurate and the time and labor saved in employing the shorter form far outweighs the slight increase in accuracy of the results if calculated from the exact formula. The error in the results between the two formulas is negligible in the long run, except when $Q$ is very small, as the natural error in estimating an average or representative demand figure $Y$ will wholly counteract this discrepancy.[3]

The theoretical formula for the Economic Production Quantity in the approximate form and including all contributory factors and coefficients may be written as follows:

$$Q = \sqrt{\frac{FP\{2\theta Y_a - \Delta[\theta Y_a + Y'_r(f-1)i]\}}{c'i\left[(k+f-1)\Delta P - \theta Y_a\left(\frac{1-\frac{1}{n}}{2}\right)\right] + c'i.\theta Y_a\frac{k_pi}{a'} + vB\Delta\left[Pf - Y_a\left(1-\frac{1}{n}\right)\right]}} \quad \ldots\ldots[1]$$

(Approximate solution)

Even such an equation, at first thought, is open to criticism on the ground that it is purely theoretical and too complicated for the average industry, and will require too much energy and time to solve when it must be applied to a large variety of lines and a correspondingly larger number of component parts. However, upon further investigation considerable simplification is possible when applied to a given type of industry, as the various items may be divided into groups, several of which are general in their application and will reduce the formula to one having but a few special items. All terms may be arranged in four groups according to the influence of

- *a* Production or consumption rates
- *b* General economic values
- *c* The specific process
- *d* The individual part.

The resulting special formulas will be comparable to such similar ones as have been developed for a specific industry without regard to the problem as a whole. Accordingly with the application of mechanical means of solution as previously suggested the universal use of the law of Economic Production Quantity is quite practical.

### Types of Industrial Processes

In applying the law of the Economic Production Quantity to actual conditions it becomes necessary to divide industries as a whole into four types depending upon the nature of the processes involved. To the first type belong those industries which are fortunate in being able to obtain the ideal manufacturing conditions and can arrange groups of machinery or processes which will produce continuously, thereby eliminating set-up costs and bringing supervision and maintenance costs to a minimum. By a proper balancing of the units of production a steady flow can be maintained to follow closely the sales demand, and the stock held of finished articles need only be sufficient to take care of an emergency. In the case where the demand fluctuates due to seasonal variations it may be necessary to maintain additional articles in stock in excess of the reserve stock to smooth out irregularities in the demand, and this will require a larger inventory. Either of these conditions, however, is preferable, in the light of final costs, to intermittent periods of production.

To the second type of industry belong those having a more varied line of products and a diversified sales demand and to which continuous production cannot be applied in full as the number of units produced would exceed the sales. It may, however, be applied in part, production then proceeding at a semi-continuous rate. The nature of the process is such that the articles can be manufactured at a continuous rate for a stated period and withdrawals from work in process can be made to meet the consumption during that period, the remainder of the work in process being then placed in stock to supply future demands. Provision must be made for a larger stock to be carried than in the first case, which naturally increases the investment in inventory. The production periods for the same article are repeated at intervals; meanwhile the machine equipment is shifted to the production of other articles of a related nature, and will be again used to produce the original article when the quantity in stock has reached the order point.

The third type of industry can in no way take advantage of continuous production, and therefore no material can be withdrawn from work in process to meet sales until the whole number of articles being processed is entirely completed. The inventory problem now becomes more complex as the entire number of finished articles must be placed in stock before they are available for consumption, and a definite order point with its minimum stock must be maintained, as well as a reserve stock to be used in case of emergency. However, if the various operations composing the process can overlap, groups of articles can be processed in such a manner that as soon as the first group or batch comes off the last operation it can be withdrawn from work in process and placed in stock, thereupon being available to meet consumption. By this means the industries in this class can approximate the condition of industries of the second type, and will be considered as operating on the principle of batch production. As in the second case, the machine equipment is shifted from one process lot to another, each lot being composed of similarly related articles, until it is time again to replenish the stock of the original article.

A fourth type of industry is represented by the job shops where all articles are produced in small or unrelated quantities at irregular intervals or are never to be produced again. The preparation and supervision costs amount to a large proportion of the unit cost, and no stock is kept in stores as the completed lot is immediately shipped to the customer who assumes the storage responsibility.

### Analysis of Factors

Following out this grouping of the various types of industry, an analysis can be made of the theoretical formula [1], which will demonstrate the influence of each term on the result and establish the limits within which such terms may be varied by specific conditions. For example:

[3] The practical limits of use for the approximate solution are excellently discussed in an article by George Pennington, published in *Manufacturing Industries*, March, 1927.

*a* If the production rate $P$ is omitted from the formula, no allowance has been made for the effect of the manufacturing period on stores, or the expression for $Q$ is being used to control purchases.

*b* If the consumption rate $Y$ appears to be zero, no definite sales demand exists, individual orders are received for stated quantities, and shipments are made as specified. No application of the principle of economic production quantities can be made under these circumstances, as the industry is a jobbing shop of the fourth type.

*c* If the stock coefficient $k$ is zero, no stock is held to offset the sales, as the conditions are the same as above. If $k$ equals one-half, the consumption is uniform; if $k$ is less than one, but not equal to one-half, the consumption rate is variable; and if $k$ equals one, there is no consumption, and the industry is performing a storage function, such as a warehouse, and maintains the articles in stores for a definite period of time.

*d* If the reserve stock factor $f$ is zero, the industry is operating on continuous production, if $f$ is less than one, a small minimum stock is held—insufficient, however, to cover the consumption during the manufacturing period up to the first delivery to stores from work in process; if $f$ equals one the full requirement for the minimum stock exists, affording complete protection during the manufacturing period; and if $f$ is greater than one, a reserve stock is also maintained to meet emergencies.

*e* If the preparation cost $F$ is zero, the industry is operating upon continuous production, and if it has a finite value the industry is operating upon the principle of economic production quantities.

*f* If the production cost $c'$, including material and labor, is zero, the industry is performing a service and is not producing a finished product; but if $c'$ equals $m$ (the material cost), all the labor is applied to preparing the process which takes care of itself when production begins. This condition would exist in a chemical industry, where no direct labor is added to change the condition of each unit, and where the labor cost is independent of the units produced.

*g* If the batch factor $n$ is zero there is no production, and the formula for $Q$ is used to control purchases, except where partial shipments of raw material are made over a period upon a single purchase order. If $n$ equals one, all articles are produced in one lot and delivered to stores at the end of the manufacturing period; if $n$ is greater than one the production is intermittent, and each lot is divided into batches; if $n$ is infinite the production is continuous.

*h* If the operation factor $a'$ is less than one, the various operations overlap and all lots are divided into batches; but if $a'$ equals one, the special case exists where all operations follow in sequence, $t_1$ equals $t'$, and if they are considered as one operation, $t_1$ equals $t'$ equals $T_p$.

*i* If the coefficient of obsolescence $\theta$ equals unity no allowance is made for this condition; if $\theta$ is less than one the quantity manufactured will be insufficient to meet the current demand, showing that the factor has been wrongly determined; if $\theta$ is greater than one, the fractional part of the remaining demand has been properly distributed to meet the full requirements up to the time of obsolescence.

*j* If the coefficient of deterioration $\Delta$ equals unity, no allowance is made for this condition; if $\Delta$ is less than one, deterioration is properly accounted for.

### Existing Formulas

Simple expressions for the Economic Production Quantity have been developed from time to time to meet the requirements of a specific industry, but no one of them includes all the factors which govern the problem, so that none of these can be used as a general formula embracing all conditions that could possibly arise. The most common forms that exist are:

$$Q = \sqrt{\frac{2FY_y}{c'i_s}} \text{ (Approximate form)}$$

and

$$Q = -\frac{F}{c'} + \sqrt{\left(\frac{F}{c'}\right)^2 + \frac{2FY_y}{c'i_s}} \text{ (Exact form)}$$

where $Q$ = the Economic Production Quantity (pieces)
$F$ = preparation costs (dollars)
$Y_y$ = demand (pieces per year)
$c'$ = direct cost, including labor, material, and overhead (dollars per piece)
$i_s$ = the investment-rate charge composed of an interest rate, the storage charge distribution rate and a rate representing the unit allotment of taxes, insurance and general expenses (per cent).

The most common variations appear in the terms $Y$ and $i_s$, as the period of time may be expressed in terms of days, weeks, months, or years, with appropriate corrective factors. It also has been the practice to express the number of pieces in units of thousands.

### Determination of the Ultimate Unit Cost

The actual determination of the ultimate total unit cost of any part or article or class of product depends upon two fundamental factors. The first, representing the direct cost of material and labor, with an overhead allowance, is common to all cases and is specifically governed by the laws of scientific management. The second, representing the investment charges on capital involved in work in process and in inventory, and the rental and maintenance charge on manufacturing and storage space, which increase in importance as the production methods become less flexible and more unlike the ideal conditions of continuous production, has been a study for financial experts and accountants. In order to balance inventories with sales demand and control inventory values, which should not exceed the accepted relation of approximately 25 per cent of the total capital worth, these factors must be expressed and combined in a relation representing the total unit cost of any product which can be solved for its Economic Production Quantity.

### Manufacturing Cost

The production cost of an article $c'$ is composed of the unit material cost $m$, plus the unit labor cost $l$, plus the unit allotment of overhead on operating time $o$, and can be expressed by

$$c' = m + l + o$$

or

$$= m + \Sigma h(d_l + d_o)$$

if the labor and overhead items are reduced to terms of the sum of all the production time per piece $h$, the hourly labor rates $d_l$, and the burden rates $d_o$ of each department involved.

The preparation cost $F$ is a fixed charge against the whole order irrespective of the number of parts produced upon the order, and is composed of various factors which include the expense of specification writing and drafting-room work ($D$) peculiar to each order, planning and scheduling of the order ($G$), issuing of the order ($O$), tool preparation ($T$) including special, tools, and machine set-up ($S$). It cannot be reduced to a unit value independent of the quantity $Q$ and therefore must be expressed by

$$\frac{F}{Q} = \frac{D + G + O + T + S}{Q}$$

The manufacturing cost $c$ includes the cost of production with that of preparation, and when reduced to a unit cost may be expressed by

$$c = c' + \frac{F}{Q}$$

This equation is not a straight-line function and approaches certain asymptotes as limits (Fig. 1) when plotted with quantities of production as abcissas.

### Investment Charge on Inventory

The investment charge $I_s$ on capital involved in inventories is quite a complex factor as it depends upon the average quantity in stock $S_a$ for a given sales period $T_s$, and is the result of balancing the demand with a reasonable production schedule, to which is applied an interest rate $i$ also composed of several factors, together with either the total unit cost $U$ or the simple manufacturing cost $c$, depending on whether an exact or approximate solution is desired. Accordingly the expressions for the investment charge on inventory can be written (see Fig. 2).

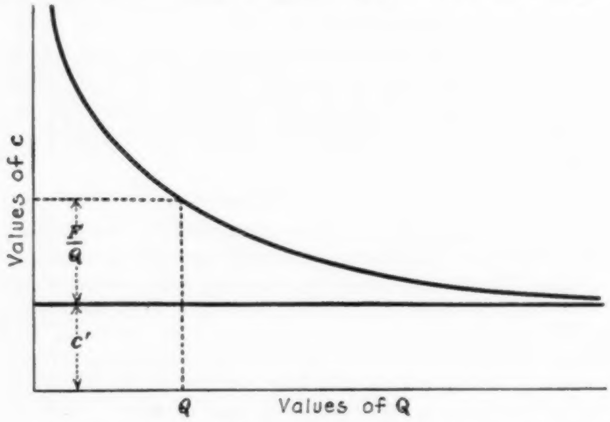

Fig. 1 Manufacturing Cost ($c$)

$$I_s = S_a \times c \times i \times T_s \qquad \text{(Approximate form)}$$

or

$$= S_a \times U \times i \times T_s \qquad \text{(Exact form)}$$

These expressions are straight-line functions of the production quantity $Q$ and the cost $c$ or $U$ in terms of dollars, and, when plotted with $Q$ as abscissa and $c$ or $U$ as ordinate, show that the investment charge increases steadily as the quantity of production increases.

### Length of Sales Period

Before the expressions for the average stock can be derived it will be necessary to consider the terms representing the sales demand and the length of the sales period. Sales records of previous years when referred to will give ample data for determining the necessary figures for the consumption rate; however, as this is usually expressed in terms of pieces per year $Y'_y$, it should be reduced to a common factor of pieces per day $Y'_d$ as an average for the year. This method takes no account of seasonal fluctuations or the general trend of the industry which will of necessity be considered later on, and for the present only an average demand $Y_a$, in terms of pieces per day, will be used. The duration of the sales period $T_s$ expressed in days is not an independent variable as it is controlled by its relation to that quantity $Q$ chosen as the most desirable to manufacture in order to meet the consumption during this particular unit of time, and cannot be reduced to an exact value until the actual value of the production quantity $Q$ is economically determined. From the foregoing discussion the following expression may be derived:

$$Q = Y_a T_s$$

for the quantity $Q$ was produced to meet the demand $Y_a \times T_s$ and must be exhausted when the period $T_s$ is at an end.

Hence

$$T_s = \frac{Q}{Y}$$

### Average Stock

The form of the expression for the average stock $S_a$ depends upon the type of industry in question. In the case of the first type operating at continuous production,

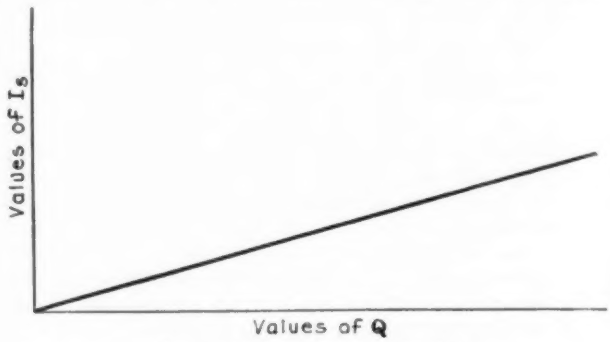

Fig. 2 Investment Charge ($I_s$)

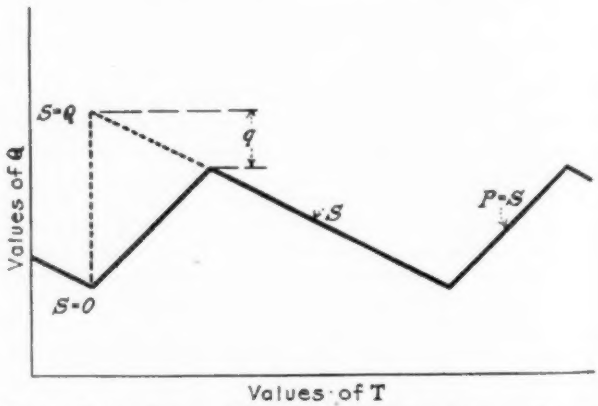

Fig. 3 Stock Curve: Semi-Continuous Production, Uniform Demand—Case II

$$S_a = 0$$

as there are no periods without production during which stock need be maintained to meet sales. In the case of the second type of industry, where continuous production proceeds at stated intervals, there is a time when articles are withdrawn directly from work in process for which it is necessary to make an allowance. The final quantity in stock at the end of the production period is equal to the production quantity $Q$ less the number of articles withdrawn during that period, which can be expressed by

$$q = Y_a \times T_p$$

where

$$T_p = \frac{Q}{P}$$

and represents the time required to complete production. The expression for the average stock then becomes

$$S_a = \frac{Q - q}{2} \qquad \text{(Fig. 3)}$$

$$= Y_a\left(kT_s - \frac{T_p}{2}\right)$$

$$= Q\left(\frac{kP - Y_a \times {}^1/_2}{P}\right)$$

where $k$ = the coefficient $^1/_2$ applied to articles in stock.

The effect of the allowance for the manufacturing period is to reduce the investment charge, but this advantage can be realized only if production can proceed continuously throughout the manufacturing period (Figs. 4 and 5). In the case of the third type of industry where there is no possibility of withdrawing articles from work in process, as all articles are manufactured

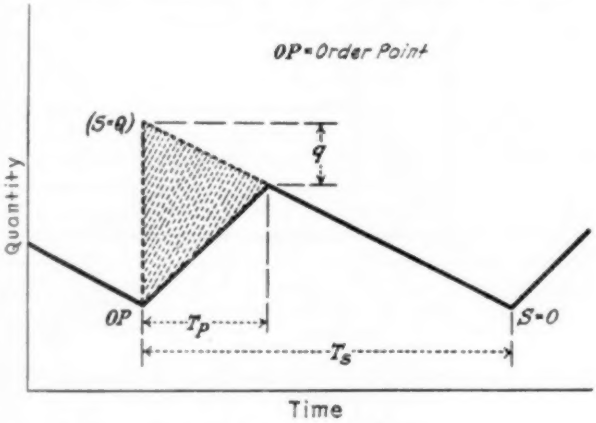

FIG. 4 SAVING BY SEMI-CONTINUOUS PRODUCTION OVER NON-CONTINUOUS PRODUCTION, UNIFORM DEMAND—CASE II

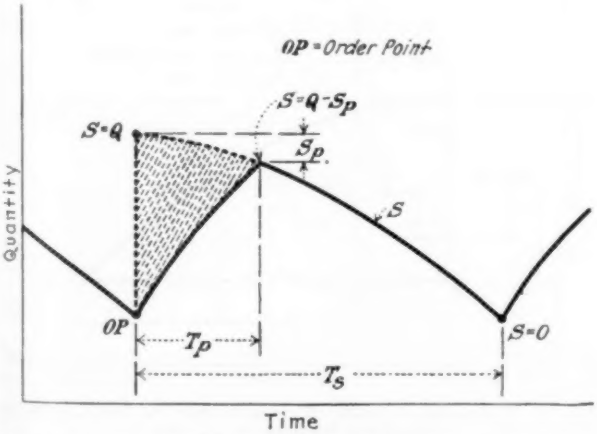

FIG. 5 SAVING BY SEMI-CONTINUOUS PRODUCTION OVER NON-CONTINUOUS PRODUCTION, VARIABLE DEMAND—CASE II

before the sales period begins, the expression for the average stock becomes simply

$$S_a = \frac{Y_a \times T_s}{2}$$

$$= Q \times k. \qquad \text{(Fig. 6)}$$

However, as indicated previously, if it is possible to apply the principle of batch production to an industry of the third type a considerable saving in investment charges in inventory can be made. This can be accomplished if the production lot be subdivided evenly into a number of batches. The size of each batch is determined by the number of pieces which can be carried in a group from one operation to another, so that each operation overlaps the other, reducing the total production time once it has been set up, and can be continuously maintained. Accordingly, once production has begun at a rate $P$, batches will be completed at uniform intervals, and thereupon will be available to meet withdrawals from stock. In other words the principle of batch production approximates the principle of continuous

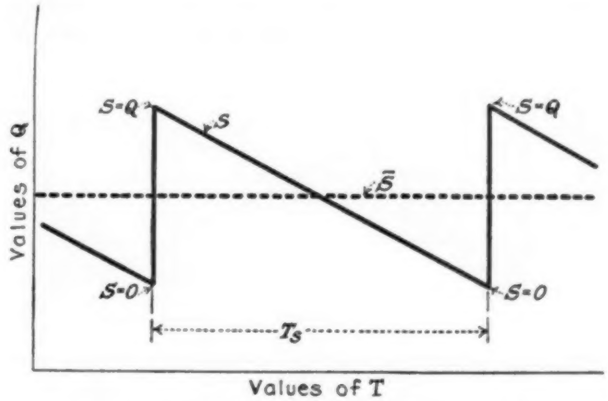

FIG. 6 STOCK CURVE: NON-CONTINUOUS PRODUCTION, UNIFORM DEMAND—CASE III$_a$

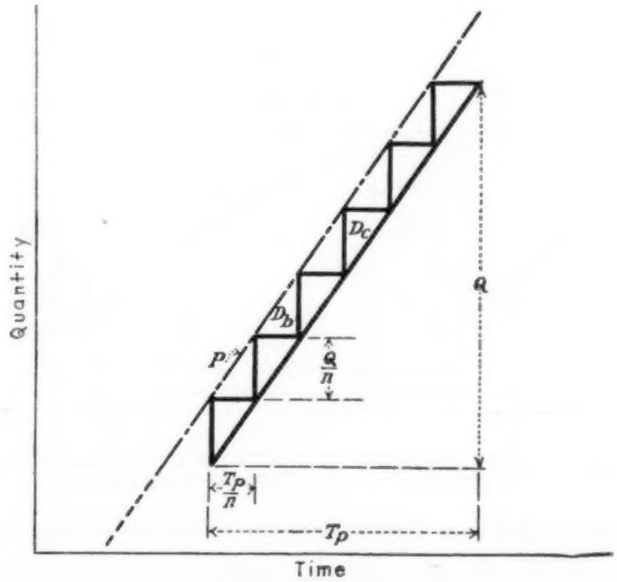

FIG. 7 DELIVERIES TO STOCK FROM WORK IN PROCESS—CASE III$_b$
($D_b$ = batch production; $D_c$ = continuous production.)

production (see Fig. 7), and if an infinite number of batches are arranged it becomes continuous production. Batch production has the advantage of reducing: first, the time required between the order point and the withdrawal of all stock; second, the minimum stock required; third, the average stock in stores during the remaining part of the production period, where it overlaps the sales period; and most important, the total investment charge. The resulting effect on the stock is shown by Figs. 8 and 9.

The method of evaluating the average stock is quite evident

from inspection of the conditions as illustrated in Figs. 10 and 11, and can be written

$$S_s = \frac{A_1 - A_2}{T_s}$$

where $A_1 = QkT_s$ and

$$A_2 = QT_p\left(\frac{1-\frac{1}{n}}{2}\right)$$

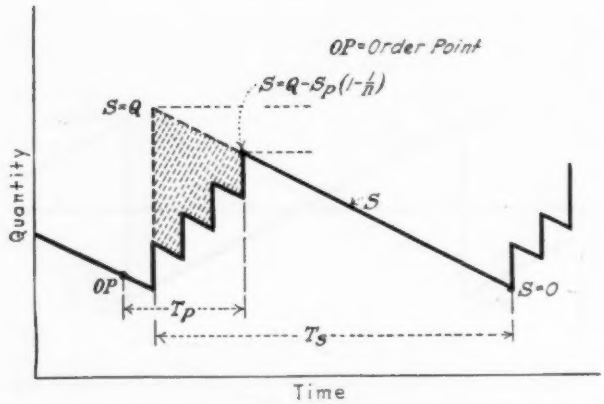

FIG. 8 SAVING BY BATCH PRODUCTION OVER NON-CONTINUOUS PRODUCTION, UNIFORM DEMAND—CASE $III_b$

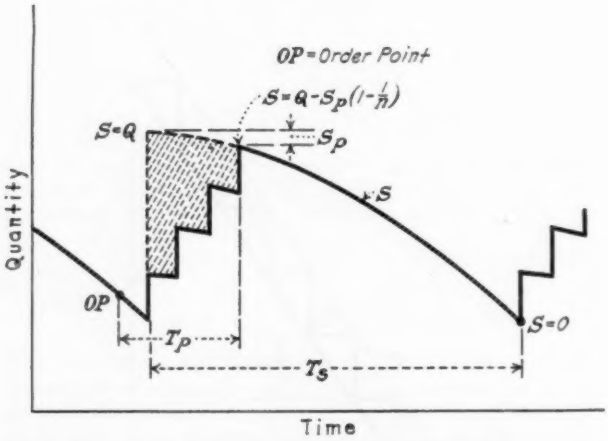

FIG. 9 SAVING BY BATCH PRODUCTION OVER NON-CONTINUOUS PRODUCTION, VARIABLE DEMAND—CASE $III_b$

Substituting these terms in the above equation and reducing,

$$S_s = \frac{Q}{T_s}\left[kT_s - T_p\frac{\left(1-\frac{1}{n}\right)}{2}\right]$$

$$= Qk_s, \text{ where } k_s = \frac{kT_s - \frac{T_p}{2}\left(1-\frac{1}{n}\right)}{T_s}$$

Again for industries of the fourth type the value $S_s$ of the average stock is zero as the storage obligation does not exist.

A general expression for the average stock may be written with a new coefficient $k_s$ which will represent the condition of the inventory in any kind of industry; hence if

$$k_s = \left(kP - Y_s\frac{\left(1-\frac{1}{n}\right)}{2}\right)\frac{1}{P}$$

$$S_s = Qk_s$$

### Reserve Stock

In certain types of industry where an unforeseen change in the demand might arise, it is advisable to maintain a reserve stock in excess of the stock required to meet the expected consumption, and this phase of the problem has been discussed by R. C. Davis in *Management and Administration*, April, 1925, wherein a formula was developed which included this item. In deriving the expression for the average number of articles in

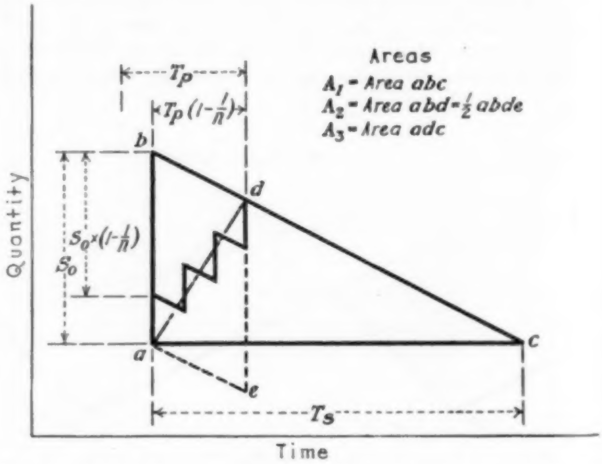

FIG. 10 BATCH PRODUCTION: DETERMINATION OF AVERAGE STOCK, UNIFORM DEMAND—CASE $III_b$

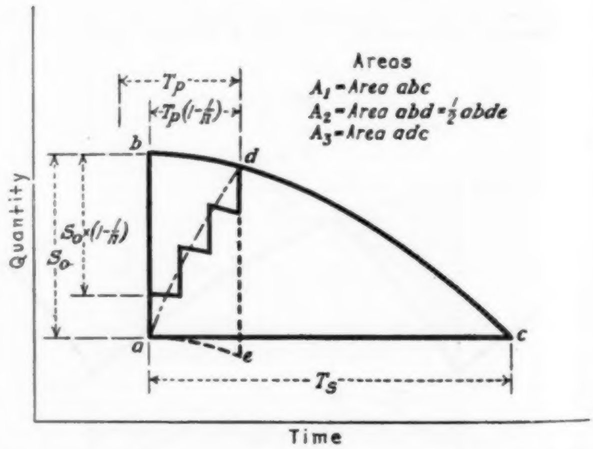

FIG. 11 BATCH PRODUCTION: DETERMINATION OF AVERAGE STOCK, VARIABLE DEMAND—CASE $III_b$

stock throughout the turnover period, the total reserve stock $S'_r$ is taken as including the stock on hand at the order point, or the minimum stock held to offset consumption $S_m$ during the manufacturing period, and the special reserve stock for emergencies $S_r$. The relation of these items is illustrated in Fig. 12, and can be rewritten in a form similar to those used in this paper:

$$S'_r = S_m + S_r \quad \text{and} \quad S_r = S'_r - S_m$$

As $S_r$ and $S'_r$ are arbitrary quantities they can be expressed in

terms of the definite quantity $S_m$ by applying a coefficient $f$, and then the relations become

$$S'_r = S_m f$$

$$S_r = S_m(f-1)$$

As long as the minimum stock does not exceed the total reserve stock the coefficient $f$ is greater than one, and the term $(f-1)$ is positive, showing that there is a quantity remaining indefinitely in stores to meet emergencies. However, if for some reason a change in the demand has caused an excessive withdrawal of articles from stock, the total reserve stock may be reduced so that $S'_r$ becomes less than $S_m$ and then the coefficient $f$ is less than one, and the term $(f-1)$ becomes negative. This shows that the minimum stock allowance will not last through the normal production period, and that production on a new lot must be commenced at an earlier date, due to the fact that the order point has been advanced by the withdrawal of an extra quantity which would otherwise have met the consumption up to the end of the turnover period $T_s$. It is doubtful whether any actual application of the negative value of the term $(f-1)$ would arise, as all calculations for the economic production quantity are made from known conditions and the negative value would only appear from some sudden and unexpected change in the demand. If such a change can be foreseen it can be accounted for naturally in the original estimate for the average daily demand rate $Y_a$ for the consumption period by the method of forecasting, as will be outlined later under the topic of variable demand. To complete the derivation of the terms $S'_r$ and $S_r$ it is necessary to obtain the quantity $S_m$ in stock at the order point, or that quantity which is required to meet consumption during the initial periods of production before withdrawals can be made from work in process.

$$S_m = Q - Y_a T_r$$

$$= Q - Y'$$

where $T_r = T_s - T_m$ and $T_m$ is the time required, in advance of the end of the period $T_s$, for the production of a new lot or batch.

Then
$$S'_r = f(Q - Y'_r)$$

$$S_r = (f-1)(Q - Y'_r)$$

From this the expression for $S_a$ can be obtained by the same procedure that was employed above, but where

$$S_a = \frac{A_1 - A_2 + A_3}{T_s} \quad \text{(Fig. 13)}$$

and
$$(A_1 - A_2) = Qk_s T_s$$

$$A_3 = (Q - Y'_r)(f-1)T_s$$

Then
$$S_a = Q(k_s + f - 1) - Y'_r(f-1)$$

Should the conditions for variable demand exist the value of $S_m$ can be derived from the general expression of the stock curve as given later, as follows:

$$S_m = Q - \int_0^{T_r} Y\,dT$$

### Interest Rate

The interest rate $i$ charged against capital invested in inventories represents that rate of return expected from working capital which is actively employed, and may amount to as much as 20 or 25 per cent a year, which should then be reduced to terms of days.

### Investment Charge on Work in Process

In practically all previous determinations of the Economic Production Quantity no consideration has been given to the investment charge upon work in process. During production, labor, with its accompanying overhead charge, and material are being so combined that at any given time there is a definite amount of capital $C_w$ invested in work in process, depending upon the degree of completion that has been attained up to that instant. Accordingly, the investment charge upon this capital can be expressed generally by

$$I_w = C_w i_w T_w$$

where $i_w$ equals the interest charge on the capital and $T_w$ equals the time over which the capital is employed in work in process. At continuous production the value of $C_w$ is a constant and

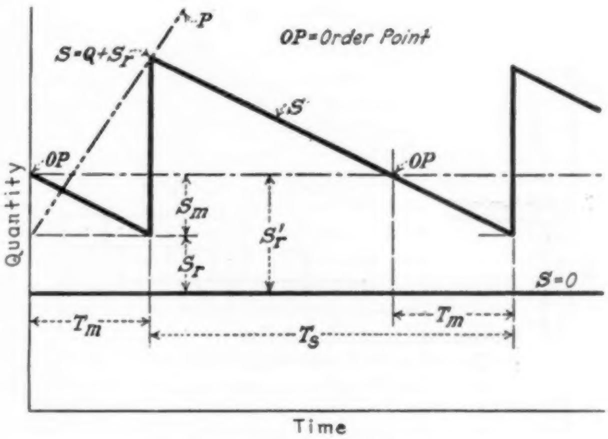

Fig. 12 Effect of Reserve Stock

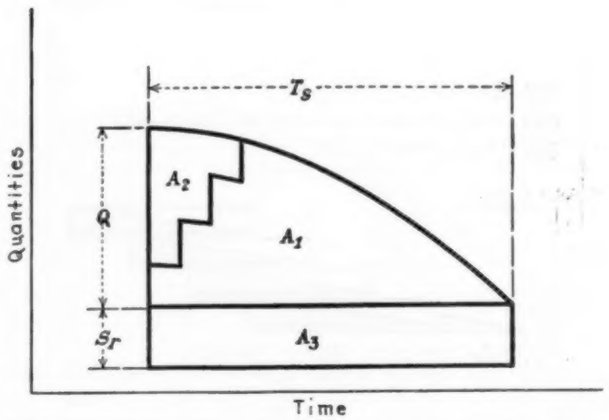

Fig. 13 Determination of Average Stock with Reserve Stock

never alters as the degree of completion of the average number of articles remains the same, one piece being started for each one completed.

Batch production, however, is so composed of a series of related operations, each having progressed to a different degree of completion at any instant, that the capital being invested in work in process is always increasing until production ceases. This can be well illustrated by Fig. 14.

Therefore it becomes necessary to determine the average amount of capital that is devoted to work in process throughout the manufacturing period. The average unit value of each batch can be expressed at any instant as

$$c'' = m + (l + o)k_s = m + hk_s(d_l + d_s)$$

The number of pieces in a batch is $Q/n$, where $n$ is the number of batches and the cost per batch at any instant is

$$c''Q/n$$

However, in order to determine the total investment charge all batches are completed in time $T_p$, and therefore the degree of completion factor is unity and the average value factor $k_a = {}^1/_2$. The cost per batch can thereby be expressed as

$$\frac{Q}{n} c'' = \frac{Q}{n}\left[m + \frac{h}{2}(d_l + d_o)\right]$$

The cost of the entire lot of $n$ batches, or the capital involved in work in process,

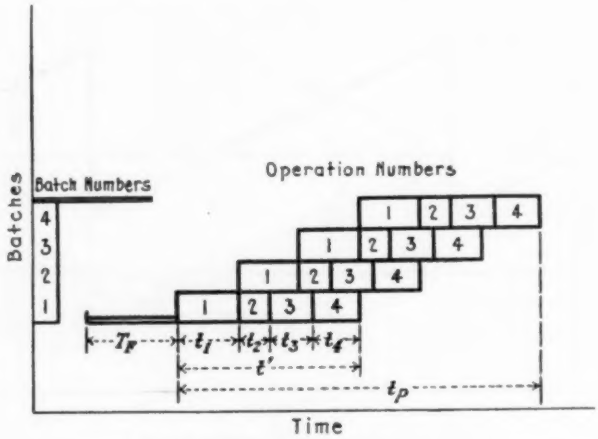

FIG. 14 THE SEQUENCE OF OPERATIONS

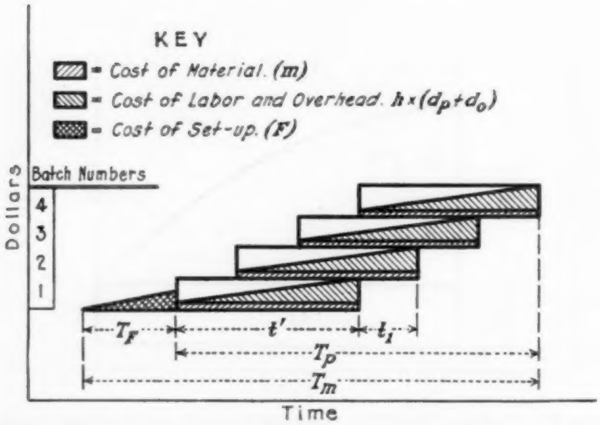

FIG. 15 THE INCREASE IN VALUE DURING WORK IN PROCESS

$$C_w = n\frac{Q}{n}\left[m + \frac{h}{2}(d_l + d_o)\right]$$

or

$$= Qc'k_p$$

where $k_p = c''/c'$. The time over which the investment charge applies is equal to the production time for each batch, including all operations, and will be designated by $t'$. The time required to complete the first operation ($t_1$) is that which separates the start of each batch. By inspection of Fig. 15 it will be noticed that

$$T_p = t' + (n-1)t_1$$

If

$$t_1 = a_1 t' \text{ where } a_1 = t_1/t'$$

$$T_p = t'[1 + (n-1)a_1]$$

$$t' = \frac{T_p}{1 + a_1 n - a_1}$$

or

$$t' = \frac{T_p}{a'}$$

where $a' = (1 + a_1 n - a_1)$. The expression for the investment charge upon capital involved in work in process becomes

$$I_w = Qc'k_p i_w \frac{T_p}{a'}$$

The interest rate $i_w$ applied to the capital in this equation is the same as used for inventories.

## SPACE CHARGE ON INVENTORY

Previously the investment charge $i_s$ on articles in stores has included several items, one of which represents a space charge based on a factor composed of rent, taxes, insurance, light, heat, etc., allotted to the stores department. This space charge should be separated from the investment charge as it depends on factors quite distinct from those governing the latter. In a paper published by R. C. Davis in *Manufacturing Industries*, August, 1926, a burden rate is applied to the space set aside for storing the maximum number of articles required to meet the consumption in any given turnover period, and the true space charge can be expressed in terms corresponding to those used in this paper as follows:

$$V = S_x B v T$$

where $S_x$ = maximum quantity that will be held in stock at the end of the manufacturing period
$B$ = space occupied by each unit
$v$ = factor representing the unit charge per day per cubic foot of space occupied
$T$ = period during which such articles are held in stock.

The maximum number $S_x$ of articles in stock, to which the factors for the space charge must be applied, is equal to the total number $Q$ of articles manufactured, minus the quantity withdrawn to meet the demand throughout the production period, plus any articles held as a reserve stock to meet emergencies, and can be expressed as:

$$S_x = Q - q + S_r$$

where the terms $q$ and $S_r$ are the same as previously derived. Accordingly this expression may be reduced, by substituting the proper values for each term, to:

$$S_x = Q\frac{Pf - Y_b}{P} + (f-1)Y_r$$

The time $T$ over which the space charge is applied is naturally equal to the length of the turnover period $T_s$ for any given production quantity $Q$, and as $T_s = Q/Y_a$ the final expression for the space charge becomes

$$V = \frac{Bv}{Y_a}\left[Q^2\frac{Pf - Y}{P} + Q(f-1)Y_r'\right]$$

However, if the space charge is applied to conditions where a variable demand exists, as will be discussed later, the expression for the maximum number of articles $S_x$ must be derived in a different manner. In this case (see later paragraph), the stock on hand at the end of the manufacturing period $S_p$ is equal to

$$S_p = Q - \int^{T_p} YdT$$
$$= Q - Y'p$$

By substituting this expression for the terms $(Q - q)$ in the previous equation, the value for the space charge can be written as

$$V = \frac{Bv}{Y_{as}} Q \left[ Q - Y'_p + (f - 1)Y'_r \right]$$

### Deterioration

Certain classes of products will deteriorate to a greater extent than others if kept in stock for too long a period or under unsuitable conditions. The loss incurred from such deterioration is justifiably chargeable against the total cost of the lot, and should be evenly distributed as an additional charge on each unit. Deterioration cannot be accurately calculated and must be estimated from experience; however, if expressed in the form of a ratio and applied as a percentage coefficient to the production quantity, a sufficiently accurate factor will be available for given conditions. Should conditions change such a factor must be altered to suit. Whenever deterioration is a vital factor experience will give reliable data. Deterioration is peculiar in one respect that it not only is a loss and an additional charge on each unit, but also requires an increase in the production quantity to make up for that loss without reducing the number of articles in stock below an amount supposedly great enough to satisfy the demand throughout the full period. The coefficient for deterioration may be expressed by

$$\Delta = \frac{Q_s}{Q_e}$$

where $Q_s$ equals the number of articles required to meet the demand $Y_aT_s$ in the period $T_s$, and $Q_e$ equals the Economic Production Quantity. Hence

$$Y_aT_s = Q_s = Q_e - Q_d$$

where $Q_d$ is the number of articles that deteriorate or are a total loss. The value of this loss depends upon the solution, whether approximate or exact, for the economic production quantity. If exact the loss $D$ becomes

$$D = Q_dU$$
$$= Q_e(1 - \Delta)U$$

If approximate,

$$D = Q_d\left(c' + \frac{F}{Q_e}\right)$$
$$= Q_e(1 - \Delta)\left(c' + \frac{F}{Q_e}\right)$$

The value for the sales period must be altered to suit the first relation and becomes

$$T_s = \frac{Q_e - Q_d}{Y_a}$$
$$= \frac{\Delta Q_e}{Y_a}$$

and this form must be used when deterioration is included in the general formula.

### Obsolescence

Obsolescence is an important factor which can affect or limit the production quantity markedly. If the turnover period extends beyond a certain limit it is quite possible, in certain lines of industry, to find that the demand will suddenly cease or alter due to seasonal conditions, improvement in design, or the whim of the customer. Therefore such articles as are not sold at that time will have no market and will remain on the manufacturer's hands indefinitely, unless scrapped for whatever value they may have. If the conditions involving obsolescence are known beforehand, the quantity to be produced becomes limited by a time factor, provided the normal sales period is greater, and can no longer be determined upon the principle of economic production quantities. This is due to the fact that the turnover period is not an independent quantity but depends upon the demand and the number of pieces produced and placed in stock. The quantity $Q_\theta$ to be produced to meet these conditions can be expressed by the relation

$$Q_\theta = Y_aT_\theta$$

where $T_\theta$ is the time at which obsolescence commences.

However, if this time limit is sufficiently remote, and yet approximately determinate, so that two or more turnover periods may pass before obsolescence becomes effective, it is possible to apply the economic production quantity methods to this case. The result is that each turnover period is slightly extended so that practically the remaining time is divided into a given number of equal periods, the quantity produced in those periods being the nearest possible to the ideal production quantity. Again it is advisable to express the obsolescence factor as a coefficient of the economic production quantity as its exact value is never known.

If $Y'_{eb}$ is approximately the number of pieces that can be sold, and $Q_e$ is the unrestricted economic production quantity, the number of whole turnover periods will be represented by

$$n' = \frac{Y'_{eb}}{Q_e}$$

The coefficient of obsolescence can then be expressed as

$$\theta = \frac{Y'_{eb}}{n'Q_e} \quad \text{or} \quad \frac{Y'_{eb}/n'}{Q_e}$$

As the only effect of obsolescence is to alter the number of pieces to be produced in a given period, it will appear only as a corrective factor applied to the time value of the turnover period. Hence if

$$Y_aT_s = Q_e$$
$$Y_a\theta T_s = \theta Q_e = \frac{Y'_{eb}}{n'}$$

but

$$\theta Q_e = Q_{eb}$$

hence

$$T_s = \frac{Q_{eb}}{Y_a\theta} = \frac{T_\theta}{n'}$$

This expression should be substituted for the usual expression for $T_s$ in the total unit cost and solved for $Q_{eb}$ which replaces $Q$ throughout without further change in form.

### Variable Demand

The rate of consumption or sales has of necessity been assumed as a definite or average amount for a year which has then been reduced to terms of a month, week or day to suit the requirements of a given formula. This practice only approximates the actual conditions in an industry as it takes no actual account of the seasonal variations in the demand nor of the major trend in that industry except as the yearly average may be arbitrarily changed. Therefore it is important that some definite method be established which will permit a correction of the demand factor to suit the changes from season to season. In certain parts of the year the demand will be great and in others it will be less, and

unless the formula for the Economic Production Quantity can take into account such differences, it will not represent that quantity which can be produced at the lowest possible unit cost. This stands to reason because too many articles may be produced at a time when the demand is slack and the investment and

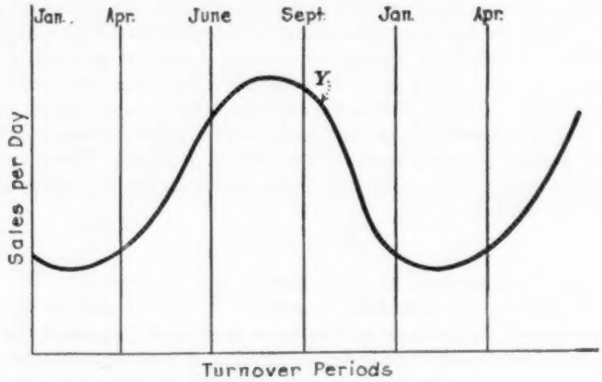

Fig. 16 The Daily Demand Curve ($Y$)

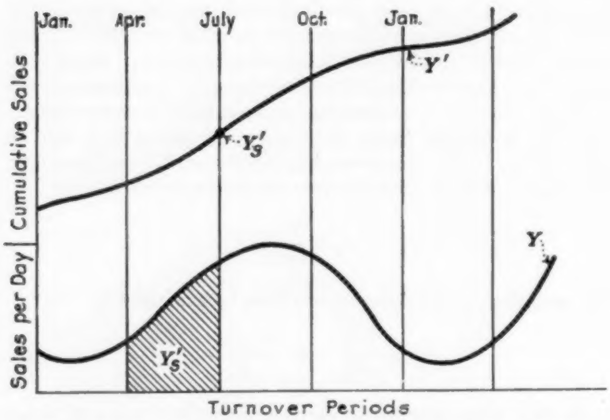

Fig. 17 The Cumulative Demand Curve ($Y' = \int YdT$)

storage charges on the finished articles in stock will be increased as they will remain in inventory for a longer time and the additional charge cannot be absorbed elsewhere. The converse will be true if the demand in a given period increases, so that an unnecessary additional process lot may be required which will involve a further expenditure of working capital sooner than ordinarily expected.

A solution of this problem is to be found through forecasting the volume of business for the immediate future. Considerable study has been made along these lines and it has been proved that reliable information and data can be obtained for determining the prospective demand for any period. The methods of making such an analysis do not concern us here as many valuable articles and books have been written on this subject, and the reader is referred particularly to two books by Mr. Joseph H. Barber of the Walworth Co.: Budgeting to the Business Cycle, and Economic Control of Inventory. The mathematical analysis based upon this work will show how the proper corrective factors may be introduced and applied to terms already existing in the formula for the Economic Production Quantity. The actual determination of these quantities involves independent calculations.

By the method of forecasting a typical curve may be obtained which will show the probable number of articles $Y$ that can be sold on any day throughout the year, which can be expressed by

$$Y = f(T) \qquad \text{(Fig. 16)}$$
$$= a + bT + cT^2 + dT^3 \ldots, \text{etc.}$$

From this, it is possible to determine the total number of articles $Y'$ required for any period which extends for a time $T$, by calculating the area under the demand curve, so that

$$Y' = \int_0^T YdT \quad \text{(Fig. 17)}$$

When $T$ becomes equal to $T_s$, this quantity represents the number of articles that must be placed in stock to meet the requirements of the consumption period and naturally must equal the Economic Production Quantity $Q$.

The expression which represents the changing condition in the stock as finished articles are withdrawn from inventory and applied to shipments may be written for any instant of time $T$, as

$$S = Q - \int_0^T YdT \quad \text{(Fig. 18)}$$

The average stock factor $k$ represents the rapidity with which articles are to be withdrawn, and is a function of the shape of the stock curve $S$. If withdrawals are greater earlier in the period than near the end, the curve $S$ is concave upward and the value of $k$ will be less than $1/2$; if the greatest withdrawals occur near

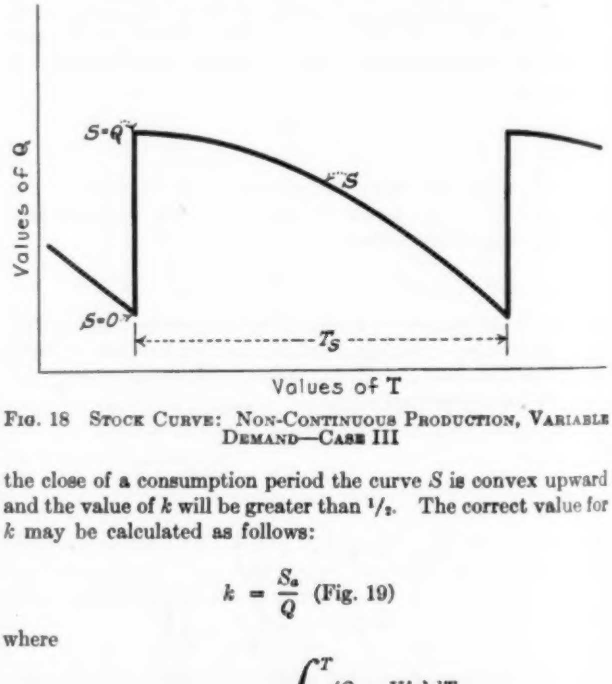

Fig. 18 Stock Curve: Non-Continuous Production, Variable Demand—Case III

the close of a consumption period the curve $S$ is convex upward and the value of $k$ will be greater than $1/2$. The correct value for $k$ may be calculated as follows:

$$k = \frac{S_a}{Q} \quad \text{(Fig. 19)}$$

where

$$S_a = \frac{\int_0^T (Q - Y'_T)dT}{T}$$

and represents the average ordinate for the curve $S$ between the limits of 0 and $T$.

The expression for $T_s$ when variable demand is to be considered can be derived from the fact that at the end of the consumption or turnover period, when $T$ becomes equal to $T_s$, the entire number of articles manufactured have been completely withdrawn from stock so that $S$ equals zero. Hence

$$S = Q - \int_0^{T_s} YdT = 0$$

$$\frac{Q}{T_s} = \frac{\int^{T_s} Y\,dT}{T_s}$$

but if $Y_{as}$ represents the average demand per day for a given period, it is equal to

$$\frac{\int_0^{T_s} Y\,dT}{T_s}$$

and can be substituted in the above equation so that

$$T_s = \frac{Q}{Y_{as}}$$

It will be noticed that both the terms $k$ and $T_s$ are dependent variables upon $Q$ and cannot be reduced to numerical values until $Q$ has been determined, as each requires an independent solution. However, a close approximation can be reached by first determining $Q$ for constant demand and solving for $T_s$ under those conditions. Then by substituting these values in the appropriate equations above, reasonable values for $S_a$ and $Y_{as}$ may be obtained, from which the desired values for $k$ and $T_s$ for conditions of variable sales may be calculated.

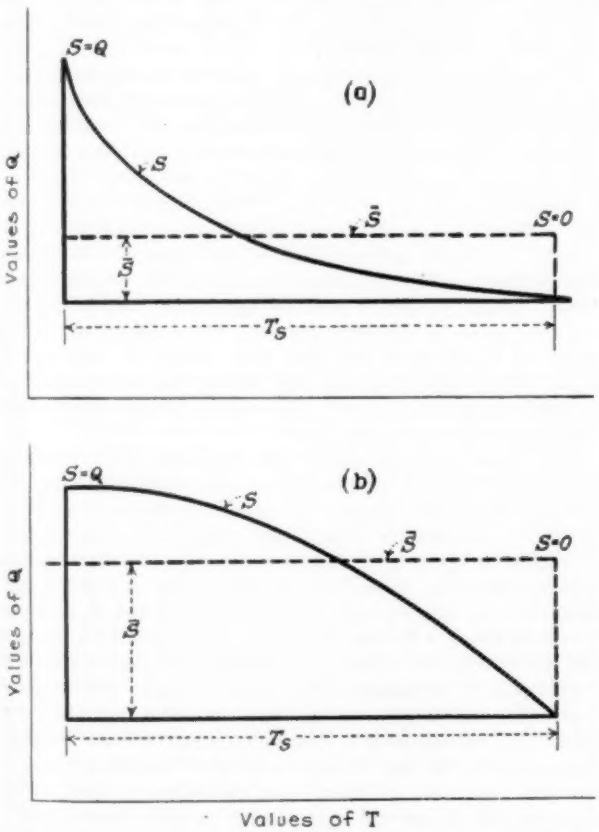

Fig. 19 Variations in Stock Curve and Average Stock, Variable Demand

This mathematical analysis is perfectly justifiable and illustrates further certain underlying factors; however, if the mathematical expressions for these factors be incorporated in the general formula for the Economic Production Quantity $Q$, the resulting equation will be so complicated that the solution will be of little practical value.

## Expressions for the Ultimate Unit Cost

Accordingly the Total Unit Cost of producing and storing manufactured articles is equal to the sum of the various cost charges derived in the foregoing paragraphs, and may be written in the following two forms, showing the relation of all items.

$$U = c' + \frac{F}{Q} + \frac{Q(k_s + f - 1) - Y'_r(f-1)}{Q}\left(c' + \frac{F}{Q}\right)\cdot\frac{i\,\Delta Q}{\theta Y_a} + \frac{Qc'i}{Q}k_p\frac{Q}{P_a'} + \frac{vB\,\Delta Q}{Q\theta Y_a}\left[Q\,\frac{Pf - Y_a\,[1-(1/n)]}{P} - Y'_r(f-1)\right] + \frac{Q(1-\Delta)\left(c' + \frac{F}{Q}\right)}{Q} \quad \text{(Approximate form)}$$

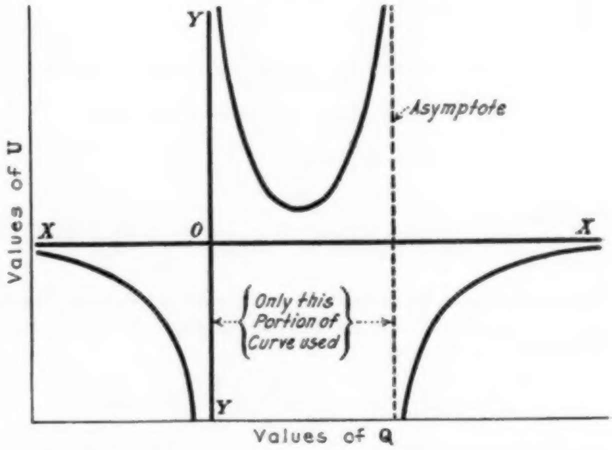

Fig. 20 Ultimate Unit-Cost Curve, Exact Form

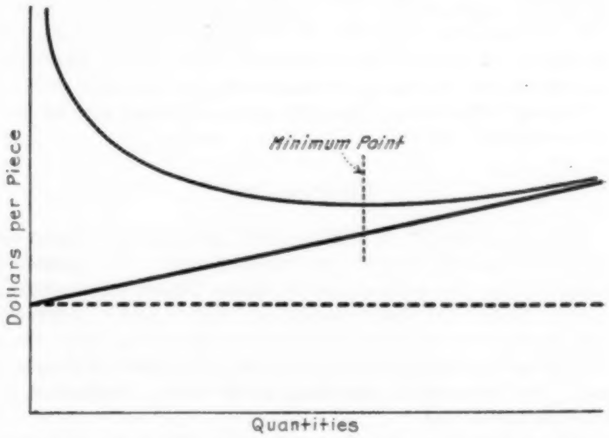

Fig. 21 Ultimate Unit-Cost Curve, Approximate Form

$$U = c' + \frac{F}{Q} + \frac{Q(k_s + f - 1) - Y'_r(f-1)}{Q}\,U\,\frac{i\,\Delta Q}{\theta Y_a} + \frac{Qc'i}{Q}k_p\frac{Q}{Pa'} + \frac{vB\,\Delta Q}{Q\theta Y_a}\left[Q\frac{Pf - Y_a\,[1-(1/n)]}{P} - Y_r'(f-1)\right] + \frac{Q(1-\Delta)U}{Q} \quad \text{(Exact form)}$$

## Analysis of Formulas

A graphical analysis of these equations shows that the effect of adding the terms $I_s/Q$, $I_w/Q$, $V/Q$, and $D/Q$ to the manufacturing cost $[c = c' + (F/Q)]$ alters the position of the curve $c$ as

described in an earlier paragraph so that the resulting curve for values of the ultimate unit cost $U$ plotted with $Q$ for abscissa approaches, in the case of the exact solution, asymptotes parallel

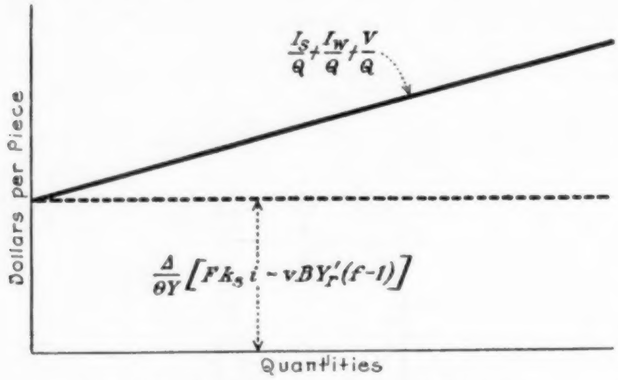

FIG. 22 INVESTMENT AND STORAGE CHARGES

to the $Y$-axis at the points where

$$Q = 0 \text{ and } Q = \frac{\Delta\theta Y_a P}{i\left[(k+f-1)\Delta P - \theta Y_{as}\frac{[1-(1/n)]}{2}\right]} \quad \text{(Fig. 20)}$$

and approaches as an asymptote, in the case of the approximate solution, a straight line inclined at an angle to the X-axis, represented by the equation

$$U = c'(2-\Delta) + \frac{I_s}{Q} + \frac{I_w}{Q} + \frac{V}{Q} \quad \text{(Fig. 21)}$$

which crosses the $Y$-axis at the point where $U = c'(2-\Delta)$ instead of approaching an asymptote parallel to the X-axis represented by a straight line $U = c'$, as in the case where $U$ equals only the manufacturing cost $[c' + (F/Q)]$. In both cases the expression for $U$, then, has a minimum point beyond which the investment and storage charges increase detrimentally without giving any added protection or business advantage and become an increasing burden.

## Discussion

JOHN C. SOMERS.[4] A definite need exists in manufacturing industries for methods of accurate measurement. The equations presented by the author give a simple means of measuring various items and then calculating, with relative accuracy, that quantity which can be produced at a minimum cost. Thus the author has made a definite contribution to industrial measurements and has assisted materially in the definite application of these measurements.

The secret of economical operation is a rapid rate of capital turnover. This is possible only with good control over raw and finished inventory. The chief advantage in the application of the author's equation is that a better control over the economics of production is obtainable, which produces similar effects in stores inventories and thus tends to speed up the rates of capital turnover. This is a decided advantage to all organizations particularly in the highly competitive field with a low margin of profit.

The writer has one criticism which is applicable to other equations in connection with the laws of management. The author points out that the solution of the general problem by minimum cost quantities has four definite applications. In any of these applications the presentation of the equation loses sight of certain aspects of the technique of solving the problem. This has reference to the terms, or combination of terms, that must be definitely determined in order to substitute into the equation. These variables, although very rarely indeterminates, require considerable skill in evaluating. The problem is admittedly simple in form, there being very definite equations for use. Nevertheless a certain amount of technique, resulting from experience, is essential to making the right substitutions. Referring particularly to the determination of fixed cost, sales demand, direct cost, and various other items, either for a specific process or an individual part, clearly indicates the obvious difficulty.

In the writer's experience, it has been useful to calculate the different values of $Q$ for the various values of the variables, such as above referred to, and then to chart these calculations for present or future use. In this way, the supply of a certain item for a definitely known period can be easily determined and economically manufactured with a single set-up. The quantity could be calculated for certain conditions, a slight variation in the conditions having a marked effect on the value of the minimum cost quantity.

In making these calculations, it must be remembered, that, in a great number of cases, the value $Q$ is the output, for a certain period, of only a percentage of the machinery that could be used. Hence the unit cost, including labor, material, overhead, preparation, and investment charges on inventory and work in progress, is somewhat fictitious, since there are additional items of cost that will add to the final cost as well as decrease the profit margin. In the larger organization, for example the electric manufacturer, this is a serious problem as the economic production quantity may be such on paper only and in the last analysis it may be the very opposite. Reference to any of the equations for $Q$ clearly indicates this. Since the unit cost is in the denominator, thus varying inversely as the square of $Q$, a small decrease in the unit price would have a considerably larger increase in the value of $Q$.

It is more or less apparent that the difficulties of applying the correct unit cost will be less where a system of standard cost is in operation. In this case there will always be a correct unit cost available for substitution in the equation. It will invariably be up to date, that is, adjusted to suit correct conditions. However, where the manufacturing period for the minimum cost quantity will extend over a period of over one month or more, a further corrective factor should be applied. This introduces the causes of inaccurate standard costs. For the purpose of discussion of the paper it might well be mentioned that current prices of materials should be used, and not a figure that will represent a speculative profit or loss. Further, in cases where the cost of material is more than 50 per cent of the total unit cost, additional care should be exercised to see that the cost of material is not based on bulk quantity costs, using the wrong weight or other quantity units.

The importance of using some standard cost system cannot be stressed too much. Also, with the larger manufacturer these standards, say on 10 to 150 thousand items, are invaluable for other control purposes, but must be handled adeptly when substituted into an equation which will arbitrarily decide that the requirements for twelve months are to be produced in two months, say, instead of six. This point can be emphasized by stating that in the writer's experience of making similar substitutions, the cost accountant had one amount, the engineer another, and the manager still another, which, incidently, was the more accurate.

The value of $Q$, the economic production quantity, sometimes is almost an indeterminate. This is true, referring to Equation

[4] 1608 Lexington Bldg., Baltimore, Md. Assoc-Mem. A.S.M.E.

[1], when $Y > 0$, $k = 1$, $f < 1$ and $n = 1$. Consumption would either be very small here or equal to zero, there would be no sales demand, an insufficient reserve stock to take care of the manufacturing period, and all articles are manufactured in one lot and delivered to stores. These conditions are not abnormal and occur frequently in the large organizations. To try to calculate $Q$ in such instances is not necessarily of much value, since the determination of the economic production quantity can be decided upon by a knowledge of local conditions in the shop.

A definite advantage of the computations, outlined by the author, is the knowledge of valuable schedule data usually quite unknown. It gives the size of quantities which are released for manufacture in the usual manufacturer's order. These are usually set up in a practical or rule of thumb method which invariably considers only the convenience of the form of the order. A definite formula from which this quantity is determined eliminates, to a degree, this rule-of-thumb method, at the same time increasing the economics of the operating cycle of manufacture.

The introduction of such calculations sometimes overlooks the proper studying of the productive machinery. It is also easy to neglect engineering changes, necessary tests, delays, interruptions, and also inefficient operation. These factors are important and can easily unbalance the production schedules that are worked up from empirical formulas. However, the economic production quantity calculations, along scientific lines, are of value to production control. The quantities can be calculated for various demands, production rates, unit costs, engineering changes, and reprocessing of work. These can be plotted or tabulated and used in the system of production control, and can be incorporated into the current standards for such work.

J. E. Hires.[5] The author seems to have worked out a very complicated formula for determining the minimum quantity of product which can be produced at the lowest total unit cost. There are many conditions which this formula does not cover, such as sometimes found in plants manufacturing a multitude of products, each bearing a different profit per unit. Also, many manufacturers use raw materials which it is necessary to order a year or so in advance, for instance one concern uses hickory handles in its tools. Such conditions often necessitate the carrying of considerable stocks. In most cases the overhead can be divided into two classes: fixed overhead, which includes rentals, administration expense, interest on investment, insurance, etc., and unit overhead, which covers material, labor, interest on inventories and work in progress, etc. With the above overhead and with the unit sales-price, a simple formula for minimum quantity units can be derived for each article.

F. Richmond Fletcher[6] and O. Cammann, Jr.[7] From the point of view of abstract science, the author has accomplished a thorough piece of work in assembling into one formula most of the factors which determine the true economic production quantity for any industry. An abstract analysis of all of the theories involved, such as contained in the paper, had to be made to prove the mathematical correctness of the theories. Practical applications were very naturally not within the scope of the paper. The writers have attempted to find the economic production quantity for a specific manufactured article by inserting actual numerical quantities in the author's formula.

In order to have actual values to use in this formula, figures for an imaginary manufactured article were developed as shown in Table 1.

TABLE 1 DATA OF IMAGINARY MANUFACTURED ARTICLE FOR TESTING RAYMOND FORMULA

| | | |
|---|---|---|
| Material | \$0.300 | |
| Labor | | |
| Operation 1 | 0.005 | |
| Operation 2 | 0.020 | |
| Operation 3 | 0.025 | |
| Burden | | |
| Operation 1 | 0.010 | |
| Operation 2 | 0.060 | |
| Operation 3 | 0.040 | |
| | \$0.460 | $C'$ |
| Set-up, Clerical, etc. | \$1.100 | |
| Operation 1 | 2.000 | |
| Operation 2 | 5.000 | |
| Operation 3 | 0.100 | |
| | \$8.200 | $F$ |
| Storage charge per sq. ft. per day | \$0.00057 | $v$ |
| Space occupied by each unit, sq. ft | 0.120 | $B$ |
| Daily rate of production, units | 400 | $P$ |
| Average daily demand, units | 10 | $Y_a$ |
| Assume $S'_r/S_m$ | 1 | $f$ |
| Fixed charge rate per day | \$0.000333 | $i$ |
| Assume all one batch | 1 | $n$ |
| $\dfrac{\text{Material} + \frac{1}{2}\,(\text{labor} + \text{overhead})}{\text{direct cost}} = \dfrac{0.300 + 0.080}{0.46}$ | $= 0.826$ | $K_p$ |
| Obsolescence not considered | 1 | $\Theta$ |
| Assume constant demand | $^1/_2$ | $k$ |
| $t' = Q/P$ (all one batch), $Q/Pt'$ | 1 | $a'$ |
| Deterioration not considered | 1 | $\Delta$ |
| $Q - S_m = Q - \left(\frac{Q}{400} \times 10\right)$ | $Q - \frac{Q}{40}$ | $Y'_r$ |

(Since $f = 1$ in this example, $Y'_r$ drops out of the equation)

At the outset we found some difficulty in adequately defining the terms used in Formula [1]. This was undoubtedly due to a somewhat hazy knowledge of mathematics; but if the average production man is to make practical use of it, the author should include a description of the meaning of the letters or terms similar to that shown below:

$F$ = preparation cost, dollars = plan and schedule, issue order, tool preparation, set-up, etc.

$P$ = rate of production, pieces per day

$$\Theta = \frac{Y'_{os}}{n'Q_s} = \frac{\text{number of pieces which can be sold}}{\text{number of whole turnover periods} \times \text{unrestricted econ. prod. quan.}}$$

$Y_a$ = average demand, pieces per day

$Y'_r = Q - S_m$ = (economic production quantity)—(minimum stock)

$$f = \frac{S'_r}{S_m} = \frac{\text{stock on hand at ordering point}}{\text{minimum stock}}$$

$S'_r = S_m$ + emergency stock

$i$ = interest rate, daily

$C'$ = unit material cost + unit labor cost + unit overhead cost

$$k = \frac{S_a}{Q} = \frac{\text{average stock}}{\text{economic production quantity}}$$

$= {}^1/_2$ for constant demand

$$\Delta = \text{coefficient of deterioration} = \frac{Q_s}{Q_e}$$

$$= \frac{\text{number of articles to meet } Y_a \text{ in sales period of \dots days}}{\text{economic production quantity}}$$

$n$ = number of batches in one lot

$$k_p = \frac{m + (l + o)k_a}{C'} = \frac{\text{material} + \dfrac{(\text{labor} + \text{overhead})}{2}}{C'}$$

[5] Consulting Engineer, Hires, Castner & Harris, Inc., Philadelphia, Pa.

[6] Engineering Partner, Scovell, Wellington & Co., Boston, Mass. Assoc-Mem. A.S.M.E.

[7] Member of Staff, Scovell, Wellington & Co., Boston, Mass. Jun. A.S.M.E.

$A' = \dfrac{Q}{P_i'} = \dfrac{Q}{P \times \text{(production time for each batch)}}$

$v$ = factor representing unit charge per day per cu. ft. of space occupied

$B$ = space occupied by each unit, sq. ft.

$Q$ = Economic Production Quantity

The specific values shown in Table 1 were substituted in Formula [1] and the equation solved for $Q$, as follows:

plete the stock $^1/_{40}$, the inventory charges against work in process are negligible. Quantities are plotted horizontally, the quantity at $T$ representing the quantity required to meet the sales demand for one year. The cost per unit, in dollars, has been plotted vertically.

The preparation-cost curve is determined by dividing the preparation cost, \$8.20, by the quantity. This will naturally be high for the lower quantities, and low for the higher quantities.

Values for the unit cost of fixed charges on inventories, and

$$Q = \sqrt{\frac{FP\{2\Theta Y_a - \Delta[\Theta Y_a + Y'_r(f-1)i]\}}{C'i\left[(k+f-1)\Delta P - \Theta Y_a\left(\dfrac{1-\frac{1}{n}}{2}\right)\right] + C'i\Theta Y_a\dfrac{k_p}{a'} + vB\Delta\left[Pf - Y_a\left(1-\dfrac{1}{n}\right)\right]}}$$

Simplifying as $\Theta$, $\Delta$, $f$, $a'$, and $n = 1$

$$Q = \sqrt{\frac{FP\{2Y_a - [Y_a + 0]\}}{C'i[(k+0)P - 0] + C'iY_ak_p + vB[P-0]}}$$

$$= \sqrt{\frac{FPY_a}{C'i[kP + Y_ak_p] + vBP}}$$

Substituting from Table 1,

for the storage cost per unit have been computed as if the whole year's supply were manufactured at one time—that is, as if an order of 3000 units were put through the factory at once. The cost per unit to carry the whole year's supply has been plotted on the basis of an annual fixed-charge rate and an annual charge per square foot for storage. The fixed-charge amount has been divided by 2 (see $K = {}^1/_2$ in the author's formula), because the average inventory is assumed to equal one-half of the maximum inventory. The maximum requirements for storage

$$Q = \sqrt{\frac{(8.2)(400)(10)}{(0.46)(0.000333)\left[\dfrac{400}{2} + (10)(0.826)\right] + (0.00057)(0.12)(400)}} = \sqrt{55300} = 744$$

After a somewhat tedious computation, we arrived at a value for $Q$ which we attempted to check by a rule-of-thumb method similar to that which any production man would use. In making this check calculation, we began to wonder whether or not it were possible to devise a simple method of determining an economic production quantity, which would be sufficiently accurate for all practical purposes, and which would not omit any of the important variables in the author's formula.

It appears that the author does not consider the question of idle plant capacity in determining the economic production quantity, with which we agree. He starts with what he calls "direct cost," which includes labor, material, and overhead. From the overhead item he deducts fixed charges on inventories, such as interest on investment, taxes, insurance, etc., and also all storage and handling charges. Consequently, for any given article at a given time, this direct cost does not vary with the quantity produced.

The writers recognize two principal types of variable entering into the equation for the economic production quantity. The first type is that in which the unit cost decreases as the quantity produced increases, such as cost of set-up, preparation of the order, and all other operations necessary to get the order under way in the factory. The second type is that one in which the unit cost increases as the production quantity increases. It reflects the increased carrying charge on large inventories, resulting from the higher fixed charges on a greater volume produced at one time, and from the added cost of storing the product in larger quantities.

The first type of variable which the author calls "preparation cost" is a fixed amount for each order put into the factory, and therefore the preparation cost per unit varies inversely as the number of units produced on that order.

Taking the figures from Table 1, we have worked out an approximate solution by a simple graphical method shown in Fig. 23. We have assumed, as we did for the author's formula, that the sales demand is constant. As the manufacturing time is relatively small, compared to the time required to complete the stock... 

space are assumed to be needed for the entire period that the stock is held. If this does not hold true, an arbitrary reduction should be made to represent the ratio of average storage space to maximum storage space. The storage cost and the fixed charge cost may be represented by lines drawn through points

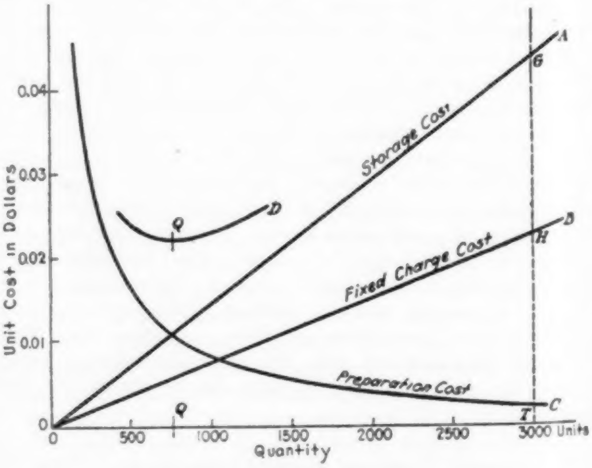

Fig. 23

$G$ and $H$, determined for one year, to the origin, because these two variables increase directly with the number of units per order.

The second type of variable, representing the storage cost and the fixed-charge cost, depends on the size of the inventory and on the length of time that that inventory is kept on hand. This charge is therefore directly proportional to the time that the inventory is kept on hand, and increases as the length of time increases.

It will therefore be seen that while an increase in the number of units on a given order will decrease the unit preparation cost, it will at the same time cause an increase in the storage and

fixed-charge costs per unit. Our problem therefore as regards these two types of variables is to determine that quantity which will reduce the unit preparation cost, plus the unit storage and fixed-charge costs, to the minimum.

If we take any given quantity shown in Fig. 23, and read off the unit cost of preparation from curve $C$, and the unit cost for fixed charges and storage as denoted by line $A$, we will have the total cost for that quantity incurred through preparation, through storage, and through fixed charges. This amount for different quantities may be plotted and a curve drawn representing such amounts, as curve $D$. This curve will invariably start at the left-hand side of the chart with a high unit cost, decreasing to a certain point, and then start to increase again as shown. When this curve reaches the minimum point (750 units approximately), as shown on the chart, it indicates the economic production quantity for the variables in question.

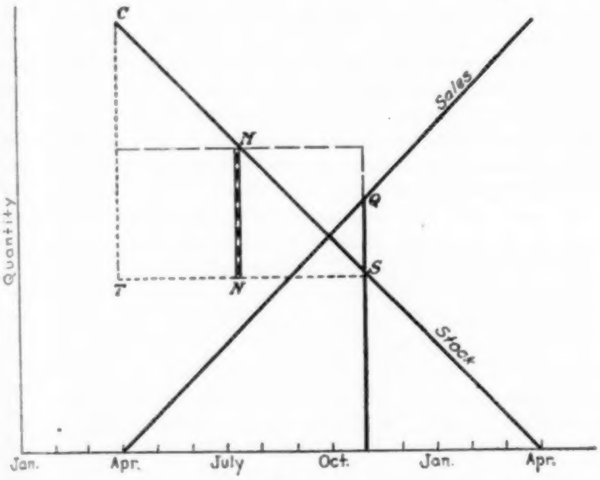

FIG. 24

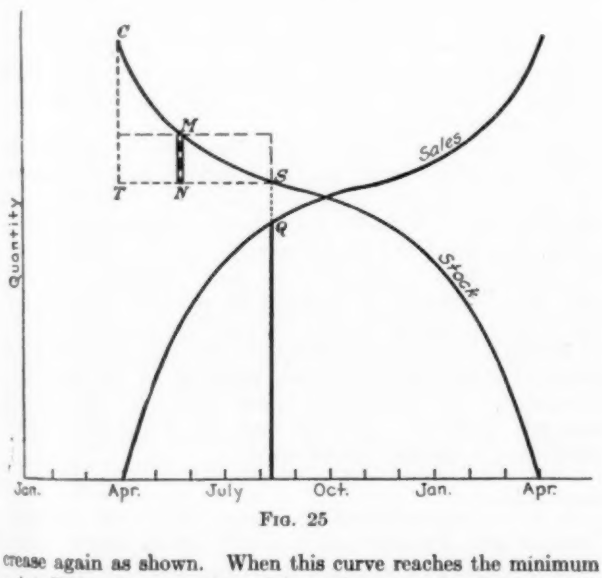

FIG. 25

The economic production quantity thus found may be affected still further by three other variables. These are the variable sales demand, deterioration, and obsolescence, as mentioned by the author.

It is obvious that if the economic production quantity results in a figure greater than that at which it is possible to sell before the article of manufacture becomes obsolete, the number that can be sold prior to obsolescence is the controlling factor, and the economic quantity is not to be considered. Likewise, if the economic quantity will produce a volume which will remain in stock longer than the nature of the product warrants, without deterioration, this will reduce the economic quantity and become the controlling factor.

The determination of the effect of a variable sales demand is somewhat more complicated than that of the other two factors just mentioned, but a solution sufficiently accurate for all practical purposes may generally be arrived at. As the author has suggested, it is advisable, first, to determine the economic quantity for a constant sales demand. Next, the cumulative sales forecast (Fig. 17) should be plotted as shown in Figs. 24, 25, and 26 and from this, the stock curve which is the reverse or complement of the sales curve. Then apply the economic quantity already computed for a constant sales demand to the cumulative-sales curve $Q$ and determine the corresponding position on the stock curve $S$. Through point $S$ on the stock curve, draw a horizontal line. The area $TCMS$ above this horizontal line will represent approximately the stock condition for the turnover period. Next, determine (visual approximation will generally be sufficient) the average volume of stock, and recalculate the position of points $G$ and $H$ on Fig. 23, for this new average stock value. The ratio of the length of the line $MN$ to $CT$ is the $K$ introduced by the author. It is used as the writers have used the factor $^1/_2$ (or divide by 2) in determining the average stock upon which to compute the fixed-charge costs.

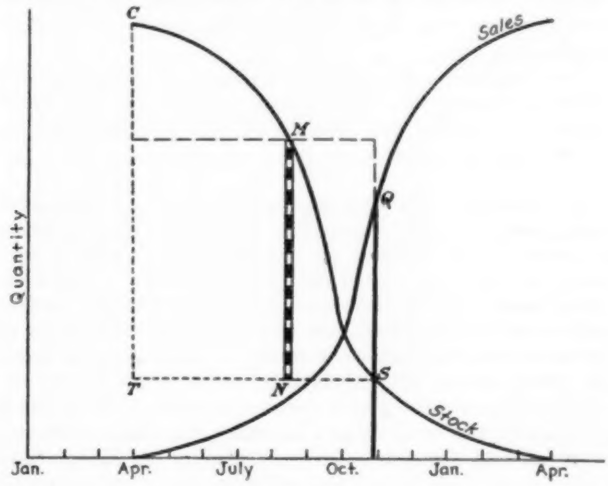

FIG. 26

The economic quantity found by this method will more nearly reflect a varying sales demand than that found by asuming a constant sales demand. It must be remembered, however, that this second solution is applicable only to periods in which the stock conditions are similar to those represented by the portion of the stock curve applying to the turnover period, although lines $A$ and $B$ in Fig. 23 are worked out for a period of one year.

As the author has endeavored to include in his formula all factors which may affect the economic quantity, some consideration should be given to the character and size of transportation devices and to the varying cost, both in labor and storage space, resulting in their use at less than normal capacity. For example, the shoe industry finds that processing shoes on racks capable of holding 12 pairs is most convenient and economical. Under these conditions if the economic production quantity resulted in the use of a 12-pair rack with only 4 pairs on it, the trans-

portation charge would be materially increased but that additional cost is not reflected in the formula.

Robert T. Kent.[3] This question of economic lot sizes is of extreme importance to executives, and we all would be deeply indebted to the man who presents a satisfactory formula to fit all conditions. One trouble with all attacks on this problem seems to be that one very practical aspect of the phase of determining economic lot sizes has been ignored. Most of the solutions have consisted in the consideration of a single item of the problem. That is all very well for the manufacturer with a single line, or a number of items of similar character. For the manufacturer who is making a rather diversified line of articles, perhaps in large quantities, for a number of different customers, the problem is somewhat complicated. Suppose that the manufacturer is making two articles in large quantities for two different customers. Each one is seasonal in character, and each has a peak which more or less overlaps the other. The machine capacity is sufficient to take care of that demand throughout the year, or perhaps throughout the seasonal period, but the situation is complicated by the fact that each customer demands deliveries to meet his sales requirements, and economic lot sizes, very often, must be disregarded in order to conform to the sales policy.

That man will make a valuable contribution to industry who devises a formula that will determine economic lot sizes, based on machine capacity and complicated by overlapping demands for that machine capacity.

The Author. The discussions submitted on my paper have added greatly to its value, one of its main objects being to gather as much outside criticism as possible, in order that it may reflect the point of view of the greatest number of engineers. Many simple expressions have previously been derived; in fact twelve writers have developed fifteen different expressions of the same general character and similar to the forms given under the paragraph on existing formulas. The graphical solution suggested by Messrs. Fletcher and Cammann is an excellent addition to the problem and simplifies the solution greatly when variable demand is to be considered. If the problem involving variable demand is worked out mathematically, the expression for $Q$ results in an equation of the sixth degree in terms of the cosine, which for practical purposes is useless. One expression naturally could be developed which would cover a multitude of products manufactured by any one company, but would probably be even more complicated than the expression for variable demand referred to above. It seems, therefore, most desirable to determine the simplest and most universal expression for the economic production quantity, applied to but one unit of the product, putting it first into a satisfactory form for practical application. The solution of the theoretical Formula [1] would unquestionably involve tedious calculation, owing to the complex composition of its terms; however, it is presupposed that this formula would be simplified to suit the conditions of any particular industry by eliminating factors and terms which do not apply, before numerical values are substituted for the remaining terms. That being accomplished, results may be obtained through simple arithmetic, in a short time.

As the purpose of this paper is to expose all controlling and contributory factors and arrange them in an expression which will illustrate their relation to each other, it was necessary to go into considerable detail in order to explain the derivation of each term. Therefore it was undesirable to give merely a list of these terms without explaining their origin; in fact half of the paper is devoted to this purpose. Naturally, considering the form in which the theoretical Formula [1] stands, special technique and understanding of the problem are required. It is hoped that in the end a form may be developed for practical purposes, requiring no special knowledge of the conditions, and resulting from these discussions and further suggestions that may be submitted.

In most cases the value used for the average storage space must be the maximum number of articles placed in stock at the end of the production period; however, should special conditions arise whereby this space is used for storing other articles after a certain number of the original articles have been withdrawn, this condition may be corrected for by a coefficient. Internal transportation does not affect the final value of the economic production quantity, because even though the total cost of the production quantity is affected by this factor which depends upon $Q$, when reduced to the total ultimate unit cost this factor becomes a constant not involving $Q$, and when differentiated, becomes zero. Likewise, idle plant capacity is not a factor affecting the economic production quantity, as accountants generally agree that the loss due to idle equipment is first, a penalty on the sales department; second, an item only of the profit and loss account; and third, one of the risks of doing business and consequently a factor not within the control of the factory management.

The present paper is only a preliminary step in consolidating all previous efforts toward deriving a suitable method of determining the economic production quantity. Naturally it is necessary first to determine the theoretical relationship of each factor, after which the theoretical form may be revised to suit the requirements of the practical plant executive. This can only be accomplished by obtaining the soundest criticism and advice from outside sources and incorporating this in our efforts. In fact such simplification has already been accomplished that a graphical chart has been drawn, including all factors except deterioration and obsolescence, from which the value of the economic production quantity may be determined without involving any calculations whatsoever.

# Training Minor Executives in a Rapidly Growing Organization

By A. J. BEATTY,[1] MIDDLETOWN, OHIO

*In this paper the author discusses the problem of maintaining a trained working force in the rapidly expanding organization. The problem of the American Rolling Mill Company is used as an illustration of what may be accomplished through proper attention to the requirements of an expanding company and to the material available in the existing personnel. Two courses organized to replace the old Works' School of the company, namely, the Operating Training Course and the Sales Apprentice Course, are described. Other means of meeting new issues in the most effective manner are presented in the author's discussion of the Foremen's Cabinet and the Foremen's Forum, the former serving in an advisory capacity and the latter as an outlet to discussion. A valuable feature of the program of developing minor-executive talent is the Armco Foremen's Bulletin, which has served to stimulate interest in the project throughout the entire organization.*

THE PROBLEM of maintaining a trained working force in a stable organization with a low turnover is a relatively simple one in comparison with that of maintaining a trained force in a rapidly expanding organization. The latter problem has been one of the urgent tasks of the personal-service division of The American Rolling Mill Company during the past five years. During this period the parent plant of the company at Middletown, Ohio, has experienced many important changes and expansions; an entirely new plant, larger than the parent plant, has been built and put into operation at Ashland, Kentucky, and the number of employees has grown from about four thousand to approximately ten thousand, a large percentage of whom, up to five years ago, had never set foot in a steel plant.

The equipment of this new plant is of a new type and design, but it has been brought into production by this almost wholly untrained working force, and has exceeded the anticipated output in quality and quantity. These results have been attained largely as the result of a very specific program of job training.

However, it is not with this job training that this paper is specially concerned, but rather with the development and the training of the necessary supervisory force for this rapidly expanding organization. The situation has demanded new foremen, new department superintendents, and a greatly increased sales force to market the increased production. It is a cardinal point in the policy of the company not to seek on the outside for a man to fill a vacancy so long as there is an available man in its employ ready for promotion.

In carrying out this policy, a large part of the responsibility of preparing men for promotion has been placed upon the training department.

Formerly the company had a training course designed for this purpose, known as the Works' School, in which were enrolled men who were headed either toward minor executive positions in the operating division or toward the sales division. But while this course was quite satisfactory for the sales division, it did not satisfy the operating management because the course was so frequently used by ambitious young operating men, with a leaning toward sales, as a stepping stone to the sales division; and to this extent the course failed to develop men for promotion to more responsible operating positions.

To remedy this defect, two courses were organized to replace the Works' School; one known as the Operating Training Course, and the other, the Sales Apprentice Course. The training of salesmen, however, is a specific story not touched upon in this paper.

In interviewing men who are candidates for the Operating Training Course, the following are some of the questions asked to determine their line of thought:

What is ahead of you on your present job?
What is the next job ahead?
What efforts have you made to fit yourself better for your work?
What study do you need to help you on your job?
Are you prepared to handle a more responsible job just now?
Has any one ever been promoted over you? Why?
What is your idea in applying for this course, and what do you expect to gain by it?
What do you expect to be doing five years from now?
What do you read?
What do you do with your spare time?
How much time are you willing to give to study to master the knowledge of the steel business?

These and other questions usually elicit answers which enable the interviewer to determine how intelligently and how seriously a candidate is considering the necessary means for his own progress. While his schooling is one of the determining factors in enrolling a candidate in the course, his experience and his record are given a good deal more weight than scholarship. Expert ability, knowledge of his job and his department, and ability to handle men are the important factors. Of the men who have taken this course about half have not been high-school graduates, about 25 per cent high-school graduates, and about 25 per cent college graduates. Several have been engineering graduates.

### The Operating Training Course

An outline of the operating training course follows.

*Function.* The function of this course is to provide that special training needed by the students to enable them to succeed to positions of responsibility in the operating division.

*Personnel.* Men are selected for this course by the works manager, or the assistant general superintendents, in cooperation with the superintendents of the departments in which the men work. They are chosen by virtue of such characteristics as ambition, interest, intelligence, health, aggressiveness, and ability to get along with people and adapt themselves to circumstances.

*Course of Study.* The course of study for each student is prescribed by the operating division management and is carried on under the supervision of the training department. When practicable, classes are formed; but in most cases instruction is an individual matter.

The general part of the course, which is required of all students, includes:

*a* Foremanship
*b* Economics
*c* Business law

[1] Director of Training, The American Rolling Mill Co.

Contributed by the Management Division and presented at the Spring Meeting, Pittsburgh, Pa., May 14 to 17, 1928, of The American Society of Mechanical Engineers.

*d* Metallurgy
*e* Business English, and correspondence
*f* Public speaking
*g* Armco products, processes, and policies.

The individual part of the course is determined by two principal factors:

*a* The specific job or department toward which the student is working, and
*b* The student's individual needs as indicated by his previous training and experience.

In the general part of this course, perhaps the most important feature is the study of foremanship with emphasis upon its relation to problems of management. The outline of the course as given in 1926 follows.

*A—The Foreman*

1 The foreman's qualities and traits
2 The foreman's job
3 The foreman as leader
4 Forcefulness
5 The foreman's prestige.

*B—Developing Men*

1 The personal-service division
2 Introducing the new man
3 Team work and cooperation
4 Correcting faults and friction
5 Developing judgment—how we think
6 Developing an understudy.

*C—Problems of Production*

1 Planning work—a daily program or schedule
2 Keeping work moving
3 Keeping up quality
4 Keeping down costs
5 Waste and its cost.

*D—Problems of Management*

1 The foreman as a part of management
(*a*) What is management in industry
2 The foreman's management responsibilities
3 Building good will and loyalty.

*E—What the Foreman Should Know*

1 Company history
2 Why men work—instincts in industry
3 "Levels of intelligence"
4 Company products
5 Company competitors
6 Company customers.

Foremanship is a required subject for men enrolled in the operating training course; for all others it is optional. A new course is outlined and followed each year in order to encourage men to continue this study from year to year.

Each September the first step in organizing for the study of foremanship is to enlist a smaller group of leading foremen—six to ten in number—which is called the Foremen's Cabinet. The men selected for this cabinet are successful foremen, judged by their record of accomplishment in getting work done and in developing men.

The Foremen's Cabinet serves in an advisory capacity to suggest and outline topics for discussion consistent with the above general outline. The Foremen's Cabinet is not a fixed group. Each member is invited to serve for three or four weeks, at the end of which time he may be dropped to make room for another man who is selected to fill his place, generally on the basis of his interest and activity in discussion groups. This plan provides enough holdover men to give a degree of permanence to the cabinet and, at the same time, the addition of new members constantly introduces new blood and new points of view.

The outline for the year being set up, an announcement of the proposed course is sent to all foremen with an invitation to enroll. Those who enroll are grouped into classes of from fifteen to twenty for round-table discussion. This course is open to all who wish to enroll.

The conference method is used. By this is meant that the chairman or leader, while he has in mind just the ground he plans to cover and the conclusions he hopes to reach, undertakes to draw out from the group members the facts and the conclusions so that whatever conclusions are reached are the conclusions of the group. He must also keep the discussion from going too far afield, and lead the group to right conclusions.

This brings up another important function of the Foremen's Cabinet, which is to train picked cabinet members themselves to serve in the capacity of group chairmen, or conference leaders.

Ranking very close in importance with our study of foremanship and management is the study of economics. This is not the study of academic or collegiate economics, but the simple and practical application of this important science. This point is appreciated by the men, as is shown in the following real colloquy reported from the plant:

"Are you in the economics class?"

"Not on your life. My job is to help run a steel plant, not a university."

"Yes, but you have been helping to run this steel plant for fifteen years now, and you have probably noticed that about ten steel plants have been started in this country to every one that is running now and paying dividends; and just about the same percentage of other businesses, grocery stores, restaurants, tire and rubber factories, building and loan associations, and even banks have failed and passed out of existence. Why? Because they didn't look far enough ahead to see what was coming."

The retort of the average foreman to this argument is likely to be, "What's that got to do with economics? That's just good common horse sense."

To which the reply is: "Exactly so, economics is simply the common horse sense which is the basis of all successful business. It is because the management of our company has always done that very thing that our plant has continued to run and allow us to keep our jobs going during the past years when other plants were shut down and their men out of work."

Such discussions as the foregoing are daily occurrences at the plant of the company and in the offices among the men who are attending the economics classes. The company believes that a stable, going business, profitable both to employer and employees, as well as to the community, can be built up only to the extent that all concerned, the employer, the employee, and the public, know, understand, and act upon sound business principles. These business principles which all must recognize and act upon make up what we call the principles of economics.

But it is not enough that the management be students of and informed upon economic laws. The company believes that its stability and growth depend upon the degree to which the entire organization, superintendents, salesmen, foremen, and workers in overalls, are posted on and act upon the economic principles involved in production, marketing, financing, capital, labor, and consumption.

The method of handling our study groups in economics is the same as that outlined above for the foremanship-management groups. Each group has a leader and an assistant leader, these being chosen partly on account of their previous training and

interest in economics, and partly on account of their recognized leadership and stability.

The director of training has a regular weekly meeting of these leaders. Here he presents an outline of the next study topic with discussion-provoking questions. In this group leaders' class are worked out the plans and methods of presenting the various topics.

The leader's job in conducting these classes is not easy. Sometimes the men have not had time to study the lessons adequately; sometimes loquacious members tend to monopolize the discussion, and usually with talk irrelevant to the lesson. Then, too, some leaders are handicapped by a purely pedagogical difficulty in not being skilful questioners.

Most of these groups meet one evening each week on their own time, the sessions lasting from $1^1/_2$ to 2 hours. The courses vary in length as follows:

| | |
|---|---|
| Foremanship, 10 weeks | Metallurgy, 72 weeks |
| Economics, 24 weeks | Business English, 16 weeks |
| Business law, 18 weeks | Public speaking, 16 weeks. |

The instructors are selected from the expert technical men in the organization, most of whom are college and engineering graduates. Some of these men are a little short on pedagogical training, but this deficiency is offset in part by a teachers' bulletin issued by the director of training, and in part by expert and practical knowledge in a specific field. Classes vary in number from three to twenty, the need for the particular class and the students' interest being the determining factor in organizing any class. Textbooks are used in metallurgy, business law, business English, and economics; and lesson assignments are made and reports and recitations are required. In other courses, text material is prepared by the training department in cooperation with instructors.

Another phase of the program for the development of minor executives is a course in company products, processes, and policies. This course is designed to give a complete picture of all departments of the plant and the part each department plays in producing the finished product. Groups taking this course are limited to fifteen to twenty, and one session of the course is given to each of ten departments, including the open hearths, the blooming and bar mill, the hot mills, the processing, the galvanizing, the finishing, the personal-service, the sales, the publicity, and the service-engineering departments.

The sessions in the production division include inspection trips through various departments, followed by discussions led by the superintendents of these departments. The sessions in the non-production departments are each in charge of a representative of that department.

Perhaps the most important part of this training course is the specific training which each man gets in the department in which he is most interested, or in which he is headed for promotion. An arrangement is made with his superintendent so that he is given special attention and opportunity to get all-round experience and knowledge of the department; he makes special studies, and finally writes a report on the department, and submits to a quiz to determine his mastery of the department, the department superintendent and the training department being the inquisitors.

Another means by which the company undertakes to develop executive talent is to keep its foremen posted on business conditions in general, and the company's business in particular. Whenever the management has any important message to get over to the organization relating either to company policies or to business conditions, or to any important change in working conditions, the entire foremen's group is called together in what is called, officially, "The Foremen's Forum."

While occasionally a set address makes up a part of this forum meeting, it is in reality a large group discussion, for it is in every sense a real forum where questions are asked, where discussion is invited, and where explanations are asked for and expected. No important move is ever made by the management in which foremen are vitally concerned and interested without calling together the Foremen's Forum to lay the matter before them, to explain the necessity and the reasons for the move, and to enlist their hearty cooperation in putting it into effect. The result of this plan is that foremen are throughly informed on proposed changes, and can help to put them into operation intelligently; and what is more important, they can explain to their men, in giving their instructions, just why the change or move is necessary. This obviates the danger of any feeling in the minds of the foremen and workers of arbitrariness on the part of the management.

Perhaps the one feature of the program for developing minor-executive talent that reaches the greatest number is the Armco Foremen's Bulletin. This is a one-page, mimeographed bulletin which is issued weekly by the training department and is sent to every foreman of the company and also to every man of higher rank than foreman.

Each bulletin is confined to a single topic of management, or of production, or of organization building, or of economics, or of personal development.

This bulletin is effective in these ways:

1 It serves as a means of carrying important announcements and items of information to foremen.

2 It is an effective forum for the discussion of organization problems, such as: "What Is the Foreman Paid For?" and "Have You an Understudy?"

3 It presents new ideas, or old ones in new garb, to keep the foremen thinking outside and beyond their jobs. "How to Handle the Boss," and "Thinking in Dollars," are examples of this type.

4 It ties in with foremen's group discussions, some bulletins furnishing the topics for discussion, such as "Encouraging Suggestions," and "Why Men Like Their Jobs." Others summarize such discussions as "What is Overhead?" and "How I Get Suggestions from My Men."

The value of the Foremen's Bulletin is suggested by the interest shown in it by foremen and superintendents. Frequently, groups of foremen are found eagerly discussing some point brought out by the bulletin, and at least two superintendents who did not sense its value at the start, and did not keep the bulletins, have since asked for all back numbers.

The one interesting bulletin that brought out a tremendous amount of plant discussion was used about six months ago in which it was assumed that a foreman was giving up his job for a promotion and he was asked to select or to recommend his successor. The employment department selected two men, giving their qualifications and their descriptions, and the foreman was asked to write back in reply to the bulletin which one he would select to take his place and why. They got a great deal and a very interesting discussion out of that.

This paper has elaborated on only the high spots in the program for the development of minor executives and supervisors and the preparation of these men for promotion. The results are, of course, hard to measure; but the best measure seems to be in the men who have moved to positions of greater responsibility through this channel.

## Discussion

R. G. Forbes.[2] The urgent need of training minor executives in our industries is apparent not only to take care of the rapidly

[2] Supervisor of Instruction, National Tube Co., Ellwood City, Pa.

changing conditions being experienced today, but to prepare for those contingencies that will arise in connection with the revolution of American industry promised us by economists in the not distant future. The writer would suggest a few questions as to the feasibility of a similar plan for industry as a whole in the hope of provoking further discussion by those interested. There are at the present time two ways in which men from the ranks are promoted to minor executive positions. The first is by fitting the job to the man, and the other is by fitting the man for the job through a carefully prepared system of training. The first method is still in common use and usually results in the promotion of a man who is either a close associate of the departmental superintendent, who in turn recommends him to the management, or one who has a record of long and faithful service in the company's employ. In either case very little attention is paid to the fundamental requirements of a succesful foreman. The result is often a barrier that arises between foreman and man that is unsurmountable. The second method is the ideal one, as the prospective foreman is trained to meet the emergencies that arise and is given a close insight into his own responsibilities in such a manner that savors of success.

The important problem of choosing the applicant for the training course has been solved to a great extent by the American Rolling Mill Company, yet nothing is mentioned as to the habit of the prospective applicant in his routine outside the mill. It appears that the industries today are demanding for their leaders men who are also leaders in the civic and social life of their respective communities, and further, men capable of shouldering the problem of home in a commendable manner. If this be true, then the applicant must be judged not only by those characteristics displayed while "on the job" but further by those that portray the manner in which he solves his obligations to his home and his community.

It would be well to include "common sense" to those requirements named in the characteristics of the applicants for the operating training course of the American Rolling Mill Company. It has been said that common sense is the ability to see things in their real light and to deal with them on the basis of sound judgment. Common sense is the monitor necessary to guide a leader out of many difficult situations. It is evident, then, that without common sense the opportunity for the success of the applicant is limited no matter what degree of ambition or aggressiveness he may possess.

The question as to the suitability of holding group meetings on the man's own time or on that of the company has long been discussed, with many arguments on both sides. If the purpose of training these minor executives in a rapidly growing industry be to fit them for their increased responsibilities in the shortest possible time, then every effort should be made to make their training period conducive to the best results that could possibly be obtained. An article appeared some time ago in *Industrial Management* showing a survey that had been made in several industrial plants concerning the efficiency of the men during the various hours of the day and night. The results pointed out conclusively that the best work was done in the morning between the hours of nine and eleven. From another source comes the information that a survey of the various colleges and universities showed that the students did their best work of the day in the morning between the hours of eight and eleven. A class in economics was held some time ago at the Ellwood works of the National Tube Company. The class convened at five-thirty in the evening. Although a standard textbook was used and the class was led by a competent instructor, yet the class terminated with but a fair measure of success, owing in large measure to a natural physical and mental reaction that set in after a hard day's work was done. It would seem, then, that the most advantageous plan would be to conduct all classes during the morning, rather than either in the afternoon or evening, and on company time, since it is evident that the compnay is more interested in developing minor executives than it is in the quantity of production of any individual during his training period.

The problem of planning the curriculum of any training course is a most important one. It would not be expected that the textile industry would include the same courses of study as the steel industry. However, there are two courses that are of basic importance in the development of any operating training course, namely, foremanship and economics. Although in some plants the phrase "minor executives" is used to include department superintendents, yet literally it embraces only foremen and sub-foremen. If this be correct it is only natural to expect that the course in foreman training be emphasized more than any other and that a greater part of the training period be utilized by this subject. In a course in salesmanship the subjects of business English and public speaking are valuable, but in an operating training course the inclusion of these subjects in the extensive manner that the American Rolling Mill Company suggests is a matter of some conjecture, as a necessary requisite for a successful foreman is his ability to converse with his men in the language of the mill and that does not necessitate the outlay of time and expense in developing complete courses in either business English or public speaking.

The effective use of the bulletin service in reaching the foremen and sub-foremen is commendable. How many of our minor executives are today going about their duties unconscious of the problems of management in which they should be vitally interested. It is quite possible to develop successful foremen, but once the foreman has passed on to his new position the problem of keeping him mentally alert and interested in his job presents itself. This can be made possible by the suggestion of problems of management, up-to-date topics of mutual interest to all foremen, and the presentation of new ideas that will give him the opportunity to enter a discussion with his fellow-foremen or his superintendent. This can be accomplished through the medium of a well-developed bulletin service.

Therefore in the planning of an operating training course for minor executives three primary factors are included; namely, the careful selection of applicants for the course, the contents of the curriculum, and the most advantageous time for conducting the classes both from the standpoint of the management and the student. Whether the development of these points by the American Rolling Mill Company presents the ideal solution can only be determined by individual considerations.

C. S. Coler.[3] This question of finding and developing men who can be executives is quite an important one in industry. It seems to the speaker that executive work requires three things: first, length of vision; second, breadth of information and experience, and third, depth of understanding of human nature.

The program which the author has outlined seems to be well calculated to develop these three things in the individual who is going to be a leader. In our modern organizations the executive is more and more becoming a professional man. He is the universal joint between capital and labor in one direction, between the seller of raw materials and the buyer of finished product in another, and between his own organization and the public at large in a third direction. The training of minor executives is primarily an executive function and secondarily an educational function. We are dealing with mature men who have a background and who have a certain standing to maintain in the eyes of their workmen.

[3] Manager, Educational Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

In our own organization our works manager selected a group of ten supervisors and worked out with them in a series of conferences a definite program of procedure for meetings which were intended to develop executive ability. Later on each of these ten men was put in as the secretary of another group of ten men, thereby bringing together ninety supervisors in the second group. They in turn worked out programs for each group intended to develop those individuals.

Some of the subjects that were covered are: The characteristics of a good supervisor, duties and responsibilities of a foreman, duties and responsibilities of a cost man, duties and responsibilities of a rate man, duties and responsibilities of an inspector, the new employee, measuring and grading employees, the problem of wages, building up and maintaining a working force, safety, control of work in process of manufacture, transportation, handling of materials, quality production, control of defective work, service department, suggestion system, and factory costs.

No standard texts were used in connection with this work, but the men used many sources of information in gathering the material, and as a result of their activities have published several pamphlets dealing with the subjects they discussed.

The older method of creating executives was fundamentally a method of sink or swim. It was competition from the word go, and survival of the fittest. In those days organizations were small, and each individual secured a sufficient variety of experience to give him the background that he needed. The individual grew as the organization grew, and oftentimes executive work was given as a reward for high-grade work in some technical line.

New conditions have brought in a longer school period, specialized jobs, a lowered discipline and urge on the part of the individual as a result of prosperity. The larger organization makes the top seem farther away for the new and younger man. And the executive has become a hired man instead of the man who owns the business.

Present methods of training have had to take these things into consideration. We are finding today that the first step is a very careful selection of men coming into the plant, so that we will have a sufficient amount of inherent executive ability in the organization to draw on in filling vacancies; then we must keep careful records and conduct reviews from time to time to detect special executive ability; finally, we should institute training courses, such as those outlined by the author, to broaden the experience of the individual.

We find that it is advisable in developing executives to start giving responsibility to men just as early as possible. The acceptance of responsibility, in fact, is the keynote of executive development.

We have been trying to build into the Westinghouse organization a substantial background for promotion into executive work through our trades training, intermediate training, and graduate student courses. The idea back of all of these courses is to give the men a broad conception of the problems involved in our organization, the products and policies of the company, and our personnel. It is a movement that is intended to counteract the effects of the movement which has been going on in the direction of more highly specialized jobs.

R. L. Kirk.[4] The company that the writer represents, being a public-utility company, does not produce in the sense that most of you do in turning out some tangible commodity. We do not have quite as many foremen, perhaps, and we may have more technical men in our organization in proportion to many of you, so that the problem of training minor executives is perhaps not as important as training the men a little higher up. I think that there is plenty of executive material around; in fact, any of you men that have had anything to do with the young boys think that all they want is to be executives, to get into the management end of the business.

The writer believes that a certain amount of luck enters into the selection of a young man or the reaching of a certain height by an executive. Suppose that in any organization you take the president away and put a new president in his place, and how many of the same staff would he select?

We have a systematic personnel department headed by a director of personnel. It seems to the writer that one of the most important things about the seeking and training of executives is to have a sympathetic attitude. Some executives carry all the burden on their own shoulders and will not let any of their subordinates do a thing. Other types of executives push it all on the subordinates and tell them to "sink or swim." The executive has to get the habit, he has to get the thought, he has to try these young fellows out. Give him an opportunity to be an executive. The Duquesne Light Company has several means of training minor executives. We operate an apprentice engineering course, in which we take men directly from college, put them through a twelve months' training period and let them seek their own level. We have departmental courses where we take college and non-college men and put them through courses in their own particular departments. We have a very liberal transfer policy. Many men come into our organization in a certain line of work where they are better fitted for other types of work, so frequently we transfer people from one department to another in trying to fit them in.

We have cooperative schools working with the university and high schools, and the trade schools, where a boy goes to school for two weeks, comes into our company and works for two weeks, goes back to school for two weeks more, etc. thereby getting our point of view and the training at the same time.

We have various types of schools in the organization. One of the steps we took last year was to organize an economic or general administrative course of economics which was open to all the members of the company. We enlarged that and made it a class for utility administration. We had 70 men enrolled there. The junior executives, the president, vice-presidents, general attorney etc. met with these men and told them their problems, a kind of an open forum. On Saturday mornings we have started something in the way of general sales classes. Our regular starting hour for work is eight-thirty. We begin these classes at eight o'clock and carry on until nine, so that half is on the company's time and half on the employee's time. We have had such a response that we do not have a large enough hall and we are putting up a building for the purpose.

Much of our training is given through the night-school work. We emphasize public speaking, and we have six or seven public-speaking classes and five or six economics classes. We have the Wranglers Group, whereby men of the same type get together and argue back and forth, so to speak.

We have the Contact Club, of about three hundred senior and minor executives, that meets once a month to discuss ways and means of doing a thing better. Last of all is the suggestion contest, and we get a lot of good suggestions. Many persons have been promoted to responsible positions because they have come before the management through suggestion contests.

J. O. Keller.[5] What a large company can do for its own supervisory personnel, The Pennsylvania State College, through

[4] Assistant to System Development Engineer, Duquesne Light Co., Pittsburgh, Pa.

[5] Head, Department of Engineering Extension, The Pennsylvania State College, State College, Pa.

its Department of Engineering Extension, has been doing for some of the smaller organizations of this Commonwealth that do not want to spend the money for a special training force. Moreover, some of the larger industrial organizations of the State that easily could afford to set up their own training organizations have also been using this special training service.

Secretary of Labor James J. Davis, in the January, 1928, issue of *Current History*, has very aptly described the conference method as follows:

"This method is based upon the idea that an experienced foreman will profit most by a supervised discussion of his problems with a group of experienced foremen. This discussion is carried on under the leadership of a chairman or conference leader who does not necessarily need to know anything of the details of the foreman's job. His principal function is to aid in the discussion by helping the foremen to organize their ideas, to analyze situations, and also to hold down discussions to the point. He acts more as a general chairman than as a teacher. This plan has extended itself rapidly during the past two years with splendid results."

Our first experience in conference training was in the last year. It has been accepted so enthusiastically by various industries that in addition to the special conference leader employed to inaugurate the work two additional men had to be secured to meet the demand.

During the past two years we have conducted 37 conference groups, all of them with excellent results, in the following types of industries:

| | |
|---|---|
| 1 Structural steel | 14 Machine tools |
| 2 Steel sash | 15 Textile machinery |
| 3 Tool steels | 16 Yarns |
| 4 Small tools | 17 Broad silk |
| 5 Saws | 18 Other textiles |
| 6 Machine shop | 19 Paper cups |
| 7 Foundry | 20 Rubber tires and tennis balls |
| 8 Forgings | 21 Cork and insulation products |
| 9 Non-ferrous metals | 22 Linoleum |
| 10 Automobile bodies | 23 Zinc |
| 11 Automobile trucks | 24 Paint |
| 12 Pressed metal | 25 Chemicals |
| 13 Ice machinery | 26 Safety appliances |

The growing popularity of the conference method is quite evident, for since we started supervisory training in 1922 we have had in addition to these 37 conference groups 68 groups of other types of foreman training.

We try to have 12 men rather than 15 to 20 in a group, although we have taken as low a number as 10 men and as high as 16. We are led to believe, however, that 12 is the ideal size for the conference leader to get the best results.

The mechanics of the conference are very important. We insist upon having the men group themselves around a long table, an arrangement which makes them feel more at ease and they are more willing to "open up" and take part in the discussion. If a table is not used, the men necessarily face each other, and they feel ill at ease, are conscious of their legs and hands, and tend to keep silent. Then a blackboard at the end of the table near the conference leader or a folio of large sheets of paper which may be torn off as they are used enables the leader to illustrate many points, draw pictures or cartoons, and list the points of the discussion as they come out of the group.

Not all men are conference leaders. We have tried to train many of our staff to act as conference leaders, but only one man out of about eighteen may be considered good enough to handle industrial groups; and then this one man must be given special training under other good leaders for about one year before he is prepared to conduct conferences in a manner that we consider a quality job. We have found that better results are secured where the conference leader has a practical background, not only in actual handling of men, but also in knowing something of the problems of the particular industry in which the training is conducted.

The success of our conference training may be principally accounted for by the care and attention with which we select our conference leaders. This careful selection may not be so essential in an organization in which the method does not have to be "sold" to an outsider; but in our work, where every small as well as large firm must be thoroughly convinced of the merit of the proposition, we have to consider seriously and carefully the selection of our conference leaders. The burden of obtaining the cooperation of the management as well as "winning over" the supervisors who are to take part in the conference, both essential to effectiveness, rests largely on the conference leader. The initial persuasion is effected by means of a demonstration conference. The conference leader must do a high-quality job on this occasion, even if the conditions are unfavorable to "put over" the conference training idea.

From all indications we expect to have our biggest year starting next fall, and already we have had requests for conferences which will keep our three men constantly busy. Other firms are indicating their desire to begin the work as soon as we can give them the time of a conference leader.

A rather interesting peculiarity about "selling" conferences is the fact that whoever gives the satisfactory demonstration is always requested by the firm to conduct the entire program. The firm usually believes that we have used our best man to demonstrate and then expect to switch to some poorer man for the actual work. We have therefore always made it a point to demonstrate with the man that we expect to use in that particular territory.

Some of the results of this method with the plants where we have done this work can be summed up under the following items:

1 Continued high interest.
2 Content matter readily absorbed.
3 Retention of the knowledge gained.
4 Assurance of the application of this knowledge to the job.
5 Development of analytical ability.
6 Development of ability to weigh facts.
7 Development of a common understanding among the foremen and other plant executives.
8 Assurance of the practicability of the content matter to the extent that it will result in ultimate cost reduction.

Arthur Williams.[6] The writer feels that the question of building a reserve force and having department heads train those under them to take their place is one of the greatest importance. The points the author has made about diversified training and the idea of discussing matters in groups also appeal to me as being finely thought out.

In the early days we leaned largely to the idea of the "born" salesman, but the supply soon gave out. In any event it is only by such thorough training as suggested by the author that the representative, whether salesman or not, can leave a lasting and convincing impression upon the customer. It oftentimes means the difference between a good opinion on the part of the latter or a bad one. Perhaps most important of all, training and procedure along the lines suggested do much to enhance among the employees that most essential of qualities, sound judgment.

[6] Vice-President, Commercial Relations, The New York Edison Co., New York, N. Y. Mem. A.S.M.E.

John D. Beatty.[7] It seems to the writer that in the smaller towns, such as Middletown, where there are one or two large manufacturing companies, the companies perform nearly all of the educational functions, while in Pittsburgh and other large communities we find that the universities and public schools are doing a great deal of the training.

We have at the Carnegie Institute of Technology 4000 night-school students who are acquiring valuable technical education for a nominal fee. The majority of these men come from about 30 of the leading firms in the Pittsburgh district. The Westinghouse Company alone has over 400 men taking vocational courses. A startling fact discovered upon registration of these 4000 students was that 11 per cent were unemployed owing to a slacking of the industries in the district. The employees' desire for an education continued, and I am glad to say that all the good men in that 11 per cent have been re-employed by the companies forced temporarily to lay them off or have been employed by another company in the same line.

Another fact discovered during the recent slowing up of business was that the college graduates held their jobs. Of this group we noticed that $^1/_{10}$ of 1 per cent were out of work in any one month as compared with 11 per cent of the non-college group.

You have been talking about foremen, men who are not educated, but industry today is demanding college men, and the colleges are becoming a testing ground not only for big executives but also for the minor executives. They say it takes 20 years to become an executive. Four years in college gives a good test of what a man will do. A recent study at the Carnegie Institute of Technology showed that the men who had a high scholarship rating and high activity rating, a good personality as we might say, were the most successful after they were graduated from school. They earned the most money and had the best positions.

All the technical schools and universities have been trying to persuade the industries that scholarship is a measure of a man's capabilities in the business world. A recent article entitled, "Does Business Want Scholars?" by W. S. Gifford, president of the American Telephone and Telegraph Company, published in *Harper's Magazine*, May, 1928, substantiates this theory.

Orlan W. Boston.[8] The author stated that 25 per cent of the students enrolled in these courses were high-school graduates and another 25 per cent were college graduates. I should like to ask if the additional four years of training in college is manifest in the results that are obtained through this foremanship or managerial course.

The writer, although interested in, has not been directly active in the matter of training for industries for eight years, but was for two years following the war. During that time Dr. Howe, president of the Case Scientific School, called a meeting of representatives of about 60 Cleveland industries to determine what the industries expected in college graduates at the time of their employment. I happened to represent one of these industries. It was interesting to learn that the majority present favored an engineering graduate who had been given a general training, that is, one who was well versed in English, perhaps a little public speaking, economics, and the fundamental subjects of chemistry, physics, and mathematics, rather than one who had specialized in any line of engineering work. It seems then that training for industries can be divided into two main phases: one is the college training needed by the industry, and secondly the subsequent training by the industry for the positions to be filled.

[7] Secretary, Bureau of Recommendations, Carnegie Institute of Technology, Pittsburgh, Pa.

[8] Professor of Shop Practice, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

I once started a statistical department in an industrial plant as a part of a program to reduce costs. I charted certain accounting-department records and mounted the charts on the wall of my office so they could be observed and studied by the employees and supervisors. Information was presented, such as attendance and lateness; costs of unit parts, such as sub-assemblies and final assemblies; departmental expenses; general costs, such as direct labor, direct material, overhead expenses, administrative expenses, and selling expenses; and cost of scrapped material. The foremen and other supervisors soon became interested in these charts, as well as in the general welfare of the company. Many additional subjects pertaining to shop practice were discussed. It was evident that by giving these administrators of various departments and divisions information pertaining to their work they were better able to direct and control their work.

I wonder if in the course of training illustrated by the author it included such items as costs; that is, if the items that enter into the cost of parts being made in that plant, such as direct labor, direct material, overhead, and so on, were given to the workmen or whether hypothetical cases were used. It seems to the writer that it is very desirable that the foremen and superintendents be given information regarding the particular industry. I think that the quickest way to gain their confidence is to make them feel that they are a part of the organization, although I know of some companies that resent that attitude.

C. P. Morrey.[9] One question has bothered our organization to some extent. We have conducted a part-time training course, apprenticeship, and on the completion of this course we aim to train the men for foremen's positions; but we found that, with the exception of one student, these men on completing their training have entered college, taking them entirely out of the field of the assistant foreman's or foreman's position, and going elsewhere for work. Also when men have been trained, has there been any difficulty in placing them in more responsible positions, and if openings are not available, do those men get uneasy and look elsewhere for work?

W. T. Magruder.[10] We know that the majority of engineering college graduates become supervisors and executives in the course of time. Their post-graduate training should therefore be with this objective ever before them. As to what may be done to help the graduate, my first answer is that he should be induced to become a member of The American Society of Mechanical Engineers, or the kindred society of whatever industry he enters. A year ago I tried to get the Council to see what could be done relative to getting a larger number of our M.E. or B.S. graduates in mechanical engineering to become members of this Society, as I was surprised to find that only from 8 to 38 per cent of those graduated in mechanical engineering are members. The same is probably true of the other professional engineering societies.

Second, he should be made interested in the work of that society. The trouble seems to be that too many of our graduates are thinking of their education as that of a trade education rather than as a professional education. The idea is, "Oh, I have my education. What more do I want?" Commencement Day is for some a "Terminus Day," educationally.

Third, they should be permitted and urged to attend local, regional, and professional meetings of their society and required to read some of the papers in which they should be interested.

Fourth, the young graduate who expects to rise and become

[9] Rhode Island Coal Co., Providence, R. I.

[10] Professor Mechanical Engineering, Ohio State University, Columbus, Ohio. Mem. A.S.M.E.

a minor executive should subscribe to at least two technical magazines in their present and desired line of work, and should read them, and thereby keep up their interest in some one branch of the profession. If they can be induced to subscribe and pay for a technical magazine, they are more likely to read it. The next best practice is for the company to subscribe to several magazines and assign to different men who would be benefited there by the reading and abstracting on the company's time of articles which should be helpful to the company.

Fifth, the young graduate and all executives should be expected to be interested and take part in some of the civic, social, charitable, religious, and recreational activities of the community, and so be a human being and a man as well as an engineer.

The author said that you never produce executives except by letting the executive produce himself. When you have the opportunity to let a man have a little chance to show his ability, as for example when a foreman is sick or on vacation, then you will find out whether a man has initiative and stamina, and if he is able to lead. You may give him a chance for two weeks in the summer-time when it is hot and the gang foreman is away. Does he run away with the job or does he let it run away with him? Does he rattle around or actually do something worth while? You can watch him and see what he does know and can do. You have to train your executives by letting them train themselves; but the way to train them is to give them a chance.

# Systems of Workman Payment in Porcelain Factories

By HOBART M. KRANER,[1] EAST PITTSBURGH, PA

*This paper describes the application of Standard Time and several other incentive systems as applied specifically to an electric porcelain plant. It points out the necessity of detailed study of the various operations in determining the applicability of the systems to these operations. It also points out the disadvantages of the simple piece-work system so much used in porcelain plants where Standard Time and other such wage-payment plans have not been studied.*

IT IS NOT the purpose of this paper to describe applications of various wage-payment plans, but to give a description of methods which are being applied in the operation of insulator plants.

The straight piece-work plan in which the workman obtains a uniform price per piece is the one generally used as an incentive for greater output in ceramic plants. The reasons for this system being used so extensively are probably that (1) the size of the organization does not warrant employment of personnel particularly well acquainted with other information along such lines, and (2) that a simple piece-work system makes calculation of the wage due the man relatively easy. Such straight piece work has the disadvantage to the workman of severely penalizing him for things often not within his control. It is impossible for a new man or one using a defective tool or die to make a reasonable wage. In the latter case it may be one of the unforeseen difficulties encountered in manufacturing. Obviously, neither of these men should be penalized by smaller wages due to these causes. Although piece work does stabilize costs and simplify calculation for the cost and payroll clerks, it is unfair to the workman.

In some porcelain plants, particularly those making dry-press porcelain, it would be difficult to form many pieces by straight piece work due to the fact that the orders are small and it would be difficult for the workman to develop technique sufficient to warrant establishing a piece-work price on certain jobs.

In one dry-press porcelain plant the management has abolished piece work entirely. They do, however, keep accurate production records and have a thorough knowledge of fair daily production on all standard pieces made. The quality of the man is subject to periodical grading according to his production records. This has the effect of giving the man fair treatment on days when he may not be feeling 100 per cent efficient or when, for reasons not within his control, he may be unable to produce an amount representative of his ability.

It is becoming more general to recognize the necessity of establishing a minimum wage whereby the workman can be assured of a minimum figure for his day's effort. An incentive for greater effort is also to be desired. Many such plans have been devised.[2]

Standard Time is an incentive system which has for a long time been satisfactorily applied to operations in large industrial plants and is now being applied with equally good results in porcelain-insulator manufacture. It is believed that the success with which this is being used warrants a description of the application.

Standard Time operates as follows:

1 All operations of a job are classified or evaluated. This establishes the quality of man required on the operation.

2 The Standard Time is the time allotted the man to produce 100 pieces on his operation. This is established by time study or experience.

3 If for any reason the man fails to meet his Standard Time he is not penalized and receives his guaranteed hourly rate. Continual failure, however, will attract investigation.

4 If the man meets his Standard Time he receives an increased hourly rate of approximately 10 per cent on his entire day's production.

The successful application of piece work or any other incentive plan such as Standard Time will depend upon:

1 Standardized methods of production
2 Sufficient production to warrant such a system.

Porcelain plants are not sufficiently perfect in these to permit a full introduction of Standard Time, as the accompanying flow sheets will indicate. The description of the application also indicates how far this plan can be introduced in porcelain manufacture.

## Plastic-Process Porcelain

*Raw Materials.* The unloading of raw materials is often influenced by non-uniformity of the clays received, whether wet or frozen, etc., and by difficulties in having cars placed properly. These conditions may affect the satisfactory application of an incentive system. The predominance of materials such as china clay, flint, and feldspar which are easily unloaded by hand methods or by the assistance of conveyor systems makes it possible to apply such systems to unloading of raw materials very satisfactorily.

*Body Preparation.* Probably the most critical of operations in a porcelain plant is the weighing of the mix. This should not be placed on any incentive system. Ball milling and blunging are operations which are governed by the time required for the equipment to prepare the material. Since this is not within the power of the men to change, these operations cannot be put on any but day work. Filter pressing, pugging, and mauling into aging cellars are readily paid Standard Time.

Pugging the aged clay into blanks for subsequent operations is another critical operation which requires the unlimited time of the men to obtain uniformity of product. This, therefore, should be done by day work.

The forming and subsequent operations of high-tension-insulator manufacture are well standardized, and Standard Time is readily applied to the hot pressing, trimming, glazing, and sanding operations. Most of these operations are done in groups or gangs in which a number of men apply their efforts simultaneously on the several parts of the major operation. For instance, in hot pressing there are mold fillers and mold runners as well as the pressmen. Each receives an individual hourly rate depending upon his work in the gang.

Placing of ware in kilns, whether this be into periodic or tunnel

[1] Ceramic Engineer, Westinghouse Elec. & Mfg. Co.

[2] "Industrial Organization," Kimball, American Management Association, 1925.

Contributed by the Management Division and presented at the Spring Meeting, Pittsburgh, Pa., May 14 to 17, 1928, of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.

kilns, is always a subject of serious consideration. Firing is approximately 30 per cent of the manufacturing cost, and it is essential that the kilns be filled as full as is practicable. Some inducement must be offered the men to utilize all the space that is available. Some plants give each of their shapes a unit value based upon their overall cubical contents, and to establish incentives for compact filling of the kiln. This method is practically identical with another which is used perhaps even more generally, in which the actual cubical content of the piece is indicated in cubic inches. The placing efficiency is then indicated in cubic inches. By so doing the men will place small pieces of ware in and around larger pieces or in other hollow pieces, thereby utilizing the kiln space to the fullest extent.

The same methods may be readily applied to the loading of tunnel-kiln cars. Here it is a matter of greater importance to the safety of the kiln and ware, however. The choice of first-class saggers and lack of painstaking placing of ware may result disastrously. It may therefore be inadvisable to place tunnel-kiln operation on any incentive plan which would appear to reduce costs unless the management can be assured of eternal vigilance on the part of the foremen in safely loading the cars to stand the trip through the kiln.

Drawing of ware is easily placed on an incentive basis. In periodic-kiln practice the kilns will average so nearly the same in quantity placed on the cubical-content or unit method that the kiln may be used as the drawing unit. Drawing as well as placing is usually a gang operation, and includes delivery of ware to the inspection department. Inspection is usually regarded as part of the firing operation and is, of course, day work.

*Dry-Pressed Ware.* The mixture for dry-pressing porcelain is prepared the same as the plastic-process material, except that the filter cakes are allowed to dry and are then pulverized. It is quite convenient to set rates on dry pressing, and this department is very readily placed on Standard Time. Furthermore, it is possible to place dry-press clay preparation on a basis whereby the cost of clay preparation is standardized. The men pulverizing and screening the clay can operate as a group and be paid in proportion to the presser's output. Trimming and glazing of dry-pressed ware are likewise logically paid by Standard Time.

*Cast Ware.* Preparation of the body for casting bushings, etc., for high-voltage use consists of weighing, ball milling, and screening. As stated before, such operations should be paid for as day work.

The making or casting operation requires that the caster work on so many different styles at the same time that it is difficult to place a rate on the respective styles in this operation. This would not be true in casting plants where one man makes only one style of piece as is done in sanitary-ware plants.

Trimming or turning of cast ware is, however, very readily placed on Standard Time for, although a man may work on a number of different-style pieces in his day, the time required for each is definitely obtained. Difficulties encountered in glazing, and care required in time handling of large cast insulators, make it inadvisable to place glazing of such large pieces on anything but day work.

### Saggers

The sagger departments of most ceramic plants are very adaptable to incentive-plan payment of labor. The preparation and making may be operated in group system. This has gone in some plants even so far as to pay men only for the dried perfect saggers upon their delivery to the placing foreman. This puts the responsibility of drying in the hands of the sagger-shop men.

### Crate Making and Packing

Packing is done in crates, thin boxes, and special thin wirewood boxes. Crates and boxes are each made by machine in several operations. Each operation is paid by Standard Time. Packing is likewise paid by Standard Time.

### Shop-Production and Loss Records

Such records are of vital importance to the cost department. In a department where sufficient ware passes to make it economical, it is most satisfactory to employ a clerk to obtain these data. Foremen in the smaller departments must be relied upon to turn in proper records by checking up on the pieces made by their men and reporting losses at each operation. Loss reports are necessary in order to obtain accurate cost data. It has been found that by pointing out discrepancies between numbers produced and losses from operation to operation, the figures given to the cost department are kept fairly accurate. For instance, if a dry presser pressed 1000 pieces and a trimmer reported 1100 trimmed, the discrepancy would be apparent. The cost department therefore has a check on the foreman on the small orders, but the overlapping of quantities in the various operations on the styles being made in large quantities makes such a check impossible there. Fortunately such larger production will bear

the expense of such clerical help, and this is of course the most satisfactory.

### Conclusion

It has been shown by the foregoing that a modern incentive payment plan can be applied to the manufacture of a wide variety of porcelain pieces. The methods described are not as yet perfected and are undergoing constant study to eliminate day work and piece work in an effort to not only reduce costs but to obtain accurate cost data.

## Discussion

Robert F. Ferguson.[3] This method is very similar to one which is fairly well established in the making of firebrick. In the firebrick industry a certain number of bricks is counted as a day's work. Whenever that number of bricks has been made, the men go home. If they make more, they get paid for more than a day's work. Take, for instance, a hand molder. If he should mold 800, he gets one and one-third pay. If he molds 600, he gets the full-day pay. If he molds his number of bricks by noon, he can go home. The firebrick plants are rather small and are pretty well under the control of one superintendent, which might make it easier than in a big plant, but this system prevails practically throughout all plants, and very few men work straight hours. In the case of hand molding, the number of bricks that the hand molder gets out and that pass the inspector sets the day's wages for everybody connected with the hand-molding department. The hand molder's rate will determine the wage for the carry-off boys and the men drying the mud and the men that wheel the clay; it is all based on the number of bricks he gets out. The only thing this is tallied is the day's production and that has to be turned in anyway. And from the number of bricks that the hand molder gets out, the wages of the clay wheelers, pan tenders, mud wheelers, and carry-off boys will all be fixed.

In setting the green brick, the number of bricks determines the wages for the green-brick wheelers and laborers connected with setting. In the case of setting intricate shapes which require care and where there is apt to be a loss to the man, a rather unique system prevails in Pennsylvania plants. The one crew will be working on the brick and several other men will be working on the shapes. There will be no time kept at all of the number of special shapes. They will divide up, and one crew will work on standard bricks and the other crew on the intricate shapes, and whatever the crew makes on the standard bricks will be paid to the crew on intricate shapes.

In wheeling burned brick a standard number of brick is the basis for a day's work. Whenever a certain number is wheeled the workmen are through. Everything is based on the 9-in. firebrick, and there is an adjustment figure for specialties. For instance, if a molder is supposed to make six hundred 9-in. firebrick, in complicated shape he might only have to make 400 equivalents, or if it is very intricate, 200 equivalents. Rates for these conditions have to be established, and are not established on the number per day, but on the basis of the 9-in. equivalents supposed to be counted for a day's work.

The same system is followed throughout the kiln firing. A man is supposed to be paid on the basis of 12 hours' time for firing a hot kiln. If the kiln is in the preliminary stages, he is credited with half-time. In other words, if he is in charge of only one fresh kiln he gets 6 hours' pay for doing 12 hours' work. If he has one hot kiln, he may get 18 hours' for 12 hours' work. If he happens to have two hot kilns, he may get 24 hours' pay for 12 hours' work. The same system is followed all the way through the manufacturing process from the green mud to the burned brick. It seems rather complicated, but when understood, it is admittedly a rather fair method.

In machine work it is not quite so easy to apply this method because there are always difficulties such as breakdowns, loss of power, belt slippage, and "galloping the goose" as we call it, which is running the clay out of the augers and back into the pug in circles. Things like that are bound to happen, so it is not easy to apply the method in a machine plant. But it is done by setting a limit fairly low so that the men can finish their day's work by three o'clock, and then, if everything goes all right and they work until four, they get more than a day's pay. We make plenty of allowances for things beyond the men's control.

There is very seldom any misunderstanding with the management and the men working close together. The firebrick industry in Pennsylvania is old, and traditions have been worked out and precedents have been established so that there are not so many questions as would seem on the surface of it. The writer thought it might be of interest to know that the author's system was not unique; but that it is one which has been pretty well established in the Pennsylvania firebrick industry.

J. B. Blewett.[4] The system that seems to appeal to some branches of the refractories work is to establish a certain amount of work with no practical limit. That is, within 10 per cent variation, a man wheels 8000 bricks for a day's work. He would not be permitted to run 8500 and he would not be permitted to work more than eight and a half or nine hours, or whatever his hours are. The object is to keep up the quality of the man's work, and to hold him to a set standard rate, and not to make it possible for him to hurry and get so much done that he can get home at noon.

P. D. Helser.[5] The author's discussion of the different systems of wage payment being used by the various porcelain factories is, indeed, very interesting. The Standard-Time system certainly has considerable merit. It would appear, however, to be more readily applicable to some branches of the ceramic industry than to others.

A large percentage of high-voltage insulators, for example, are formed by the hot-press method, which is a mechanical operation, whereas vitreous sanitary ware is made almost entirely by the casting process, which not only is a hand operation but requires considerable craftsmanship. Furthermore, in the casting process, as in all hand operations, the personal factor is involved to a very large extent. It is undoubtedly possible, however, to use the Standard-Time system in the ceramic industry much more widely than it is being used at present.

A number of the vitreous sanitary-ware manufacturers are at present using the straight piecework system of wage payment. The base rate is established by taking into consideration the skill required to make the piece, the finishing required, the weight of the piece, the conditions under which the work is done, the number of pieces that constitute an average day's work and an adequate daily compensation for the service rendered. For example, the fair rate on one piece may be 70 cents. If ten pieces are made per day the total daily wage would be $7. If, however, the pieces are very large and require considerable work and skill, a total daily wage of $9 might be warranted. If it is possible to make only three pieces per day, the rate would obviously be $3 per piece.

Some of the larger sanitary-ware manufacturers use a wage-incentive plan commonly known as the bonus system in con-

[3] Mellon Institute, Pittsburgh, Pa.

[4] McLaine Firebrick Company, Wellsville, Ohio.

[5] Eljer Company, Ford City, Pa.

nection with the regular piecework system. While it varies somewhat in detail and application at the different plants, it is essentially the same. Each piece of ware is marked permanently with the number or initials of the workman and the date made. If a workman has no loss for a period of one month he is paid a total of 10 per cent of his total earnings for that period. If he loses one piece, he is paid a bonus of 8 per cent; two pieces, 6 per cent; three pieces, 4 per cent; four pieces, 2 per cent; and five pieces or more pieces, no bonus. One company has a bonus period of two weeks instead of one month. The ware is checked through the bisque kiln or first fire and all losses for which the workmen are responsible are charged back to the men on the regular making-price basis. If there are any losses in the glost kiln or in the finished-ware stock that are obviously due to poor workmanship these also are charged back to the men. A given sum of approximately $25 is retained from each man's pay against which all of his losses are charged.

One disadvantage to this wage-incentive plan is that the men are likely to conceal defects in an effort to have no losses charged against them. Such defects may not be found until the ware is placed in service. However, the various companies that are using this plan, as well as the workmen, appear to be well satisfied with it.

W. Keith McAfee.[6] The ceramic industry is very different from a great many industries inasmuch as it is empirical; there is practically no technical control in the same sense as in most other industries. For instance, take the problem in the casting shop. So far as the writer knows, we all pay piecework, so much a piece for casting, and at the same time fix a minimum of eight hours. We tell the man that he can make only 10 or 11, depending on the particular method. In other words, there is no incentive except to make the allotted number and pass the inspection given them. The reason is simply, as has been pointed out, that the man can gloss over defects before the ware is put into the kiln, so that if the green inspector can find these defects, the loss will not be as great as if the ware had gone through the kiln. Consequently, if the barriers are taken down and a wage-incentive or a speed-incentive scheme is adopted, there will be a lot of defective ware coming out of the kiln, because the man will take a chance and patch it up and it will not be caught in the inspection, since the man can do some things to it that cannot be detected and that do not show up. It may even be something that will cause the piece to break open in the kiln. Of course, the same conditions exist in all other branches of the ceramic industry.

For that reason any wage-incentive scheme must also have a factor in it that is governed by performance. In other words, the writer personally would hesitate to put in Standard Time unless there was some factor also incorporated that had a direct relationship to the product.

The author excepts certain operations on which he says that they do not use Standard Time; for instance, in placing. The reasons given for not applying Standard Time to those operations apply to practically every operation in our own plant, with the possible exception of the bisque-ware packing department, or the like, where the work is not particularly skilled.

The two operations that the white-ware manufacturers are interested in are the making and the glazing, and those are two important places for wage-incentive schemes. How should we get a relationship between this wage-incentive system and the quality of product?

In our works we used a scheme, although we are not satisfied with it, based on the amount of ware out of the glost kiln for the month, not counting the small pieces which are not important; that is, counting the tanks, but not the lids and light escutcheons, and disregarding these because the percentage of bad ones is negligible. We count the large pieces from a half washdown up, and then add all bisque broken pieces to that. We consider that summation, arbitrarily, as the number of pieces processed. That is practically what it is, although there are some endless turns on the flow sheet, but they are relatively small. The number of "A" pieces over the number processed gives a factor that we call plant efficiency. We set a bogey of 85 per cent. That may sound low, but it is not so bad in the ceramic industry. When we exceed that figure in performance—suppose we get 90 per cent, exceeding the bogey by 5 per cent—we tell the men that we will split fifty-fifty, we will give them two and one-half per cent on their wages. That works very much the same as this by-product bonus spoken of. We have in the sanitary plant men for wheeling clay. The two and one-half per cent is very small in money, and they have little to do with performance. The dipper, who is perhaps the highest-paid man, also gets the two and one-half per cent, but it is a much larger bonus, and his workmanship is vital to performance. We pay in proportion to the skill. The scheme has worked out very nicely. We keep a daily accumulative percentage and post it on the bulletin board, and no man will pass the bulletin board without stopping to see what the curve is for that day. It creates a spirit of rivalry, even when the bonus is very small. It is as much a matter of pride as the actual money they get.

Another bonus was simply given for quantity. We had a curious experience in starting up a plant in a coal-mining district, employing mostly former miners. The hardest thing that we had to overcome was the miners' habit of not working a full week. They would work three or four days and get $6 or $7 a day and then they had enough to spend for that week and we would see nothing more of them until the next Monday morning.

Of course, in running a tunnel-kiln they cannot do this, and although every one was on piecework, and paid in proportion to the work accomplished, we could not get them to work the full week until we offered a bonus for a full two weeks' work. In other words, if the man's quota was ten a day, as it is on washdowns, and fifteen days to a pay period, if he delivered 150 past the inspector in that pay period, he got a bonus. It was not two months before every one was making the bonus. On straight piecework they would not get the ware out, but yet just the offer of this small bonus of $5 a month, or something of the kind, where their monthly earnings were $200, helped put the thing across. In about two months the casting shop had doubled its production.

In the Bausch & Lomb Company in Rochester quality is pretty much of an item. They emphasize the quality factor as well as the speed factor. In other words, the bonus is based on the savings effected rather than on the speed alone.

The trouble with this group is we are too much in agreement. I think most of us are using the piecework system and agree that it is wrong. A suggestion has been made that applied to the sanitary casting shop—that we take a piece, for instance, that pays 70 cents, and if the man makes 10 pieces he will receive a $7 wage. Suppose we cut that rate down to 60 cents a piece, and then it is quite easy from our statistics to tell how many pieces that man gets out, each piece having his number on it and the date it was made. Now suppose we paid him 15 cents for every piece that came out A grade. Then he would receive 75 cents a piece for all the ones he had made that came out A grade. Suppose it came out B. You would give him, say, 7 cents for each B that came out, and he would get 67 cents or about a 3-cent penalty on his former rate. He would not be paid anything if the piece were broken but the 60 cents that he was paid originally for the piece. Of course it raises immediately a large question when it comes out B or broken as to whether it was the fault of the man

[6] Vice-President and Gen. Manager, Universal Sanitary Mfg. Co., New Castle, Pa. Mem. A.S.M.E.

or whether the slip was bad that day, or some other condition beyond his control was at fault.

S. H. Stevenson.[7] Our company's practice has been haphazard, and it has been based, like most other dry-press porcelain plants, upon the factor of speed alone. That is we try to get as much as possible from each employee and the factor of quality has not entered in to the extent that it should. We have about come to the conclusion that in the dry-pressing of electrical porcelain, on special shapes particularly, the law of diminishing returns operates. A man can work only so fast, and when he goes beyond that limit, quality suffers. There are certain definite limits in so far as speed is concerned. As for saying that the wage system used in our plant is the right one, we do not know.

Three things enter into the setting of rates and wages at our factory; first, our labor costs must be in line with our competitors'; second, we must compete with the other industries in our locality (which in our case is the rubber industry), in order to secure the most desirable men; third, we would prefer to pay the men wages that will make them contented, and not keep them until they find some other work. In our particular plant the policy is not to employ the cheapest labor, but rather to employ the best at prices which will keep it contented and still allow us to compete. Our wage scheme is certainly far from perfect and we are groping around for a better one.

The whole object seems to be that we are all selling the public on quality; that "We are making the best there is." I have often wondered if any intelligent effort has been made to sell the workmen in the plant on quality. Are the workmen who are producing the goods consistently sold upon quality? Is an effort made to have the workmen instilled with the idea of quality? Sell quality in the plant rather than in advertising to the public. I have often wondered if other plants have tried this and what effect it has on quality.

Joseph F. Barnes.[8] Has the author ever seen a group incentive plan where a bonus was paid for quality used in the ceramic industry? I have seen that work in the by-product division of the steel mills.

As you know we all like to pick flaws in this incentive wage plan. The worst fault of the ordinary piecework system seems to be that there are two kinds of jobs, good-paying and poor-paying piece rates. Apparently this will always be true because of constantly changing manufacturing conditions. Some foremen have to be regular diplomats to keep their men satisfied. In the sanitary potteries there are many times when a workman will have some pieces to make which pay him well for his time and others which pay him but poorly. Usually the good pieces are non-competitive items on which there is a fair margin of money.

It is true in almost any industry, that is, on piecework that there are "good jobs" and "poor jobs." Even in the Standard-Time system with bonus for production there are "good jobs" and "poor jobs." That system of payment has been worked in some of the shipyards where steel erection was analyzed and a standard time and a standard price were made on an erection job. Some jobs would be good jobs, and the crew could get done by twelve o'clock and then go home at the earliest quitting time allowed, say two or three o'clock, and make a bonus too. Other jobs would be "poor jobs" and the men would work hard all day and never make a bonus. The foreman, to even things up and be fair, had to sort these various jobs and give out a good job with a poor one and the men had to take them together.

Of course much of the weakness of standard time in the ceramic industry has been due to the efforts to adapt a system developed in a background of machine operations. In many of these operations the overhead-time cost of the machine used was far in excess of the operator's earnings. There the idea of Standard Time is to put a bonus on speeding that machine up. We will say that the man gets 60 cents for a given operation and the machine-time rate—the overhead on a milling machine or something of that kind—will be worth four or five times the man's rate. To get that operator to utilize the high cost of his machine-time overhead a premium must be put on piece production. That is what is common in the automobile and other industries of this kind. Say the Standard Time is worked out so that a man gets out an average of 100 pieces and makes $6 a day. If he makes 150, not only does he get paid on the basis of 150 pieces but the rate per piece is also increased by a small bonus.

Now, obviously, in the ceramic industry that will not work, because as has been said in previous discussion, the law of diminishing returns in quality hits hard. In the sanitary pottery with a fluid-cast process the ordinary workman will make 10 or 12 washdown water closets per day. If this workman studied the elemental motions of his work and tried to make 20 washdowns a day, he might succeed, but as a large part of the work is hand finishing the quality of this handwork might suffer a lot. I believe it has been done in exceptional cases but on the average it will not. Unfortunately defects often will not appear until the piece has been dried and fired and by then the piece will have passed through five or six men's hands. It then becomes difficult to hold a particular man or department definitely responsible for the defect in question.

In a system that the writer observed in the by-product works, every one in that plant got a bonus when efficiency went above the standard value. In terms of the sanitary pottery, say that we are ordinarily producing 92 per cent A grade, if we produce 95 per cent A grade that small difference often means the difference between loss and profit. In this by-product coke works when they got a certain percentage under distillation every man got a little bonus. We will say that the fireman's bonus on maximum efficiency was about 6 cents a day while the chief chemist received around 30 cents a day. Now you will say that the chief chemist could affect the efficiency ten times as much as the fireman. However, the fireman could let the steam go down. He could affect efficiency in turn just as well as the chief chemist. This bonus was worked out on a sort of hit-or-miss value, but the fact was that the incentive was there, and the strange thing is that it worked.

I understand that the bonus system mentioned was originally adopted as part of an effort to cut labor costs. Previously this had been attempted by arbitrarily cutting a man off the payroll here and there with the result that the plant was finally actually trying to operate without enough men to do the job properly under ordinary human efficiency. The superintendent could not hire any more men, and he had to get better work, so he put a premium on efficiency, and in this case he succeeded where the attempt merely to cut down on the labor and on the overhead had resulted in trouble here and trouble there. You know what it means when you do not have enough men to do a job. You go down to the ball mills, and they are not finished. They cannot get the slip out, it will not be finished by quitting time and that means four hours' overtime—so it goes.

The writer has never seen such a group bonus plan applied to the ceramic industry.

Louis E. Smith.[9] I am familiar with several contract or incentive schemes where we take certain kinds of wages in one plant and compare them to wages on similar work in another plant. I

[7] Secy-Treas., Akron Porcelain Co., Akron, Ohio.

[8] Eljer Company, Ford City, Pa.

[9] Jones & Laughlin Steel Corp., Aliquippa, Pa.

am also accustomed to comparison of two different piecework schemes to similar work in a third plant which does not have piecework. Each of these three divisions thinks its system is best and is always anxious for cost comparisons with the others.

Any plant without a wage incentive can make a good showing against a plant using piecework by picking good foremen, paying them well, and letting them run the job, but the same plant would do even better if a wage incentive were used.

I thought we would hear a lot of argument here today; I expected some one would say that all picework is wrong when quality is considered. We have not heard any expression on that side of the subject. All these systems apply more or less. I am not speaking for myself, but I see three or four angles and wanted and expected to get them all straightened out here, and I don't believe this has been accomplished.

## Author's Closure

Inasmuch as the installation of this system was a gradual one from which each piece was studied and put under the new system individually, there was not very much trouble encountered in doing so. The system itself appeared to be more fair than the piecework plan inasmuch as the men were guaranteed a definite day rate. This is particularly valuable in cases where the man falls down due to emergencies such as power's going off.

There was little or no suspicion aroused in the installation of this system due to the fact that it is simple and the men are able to figure their wage easily. It was our aim to give the men approximately the same wage under this system as they were able to make by a fair day under the piecework system.

There were no notable changes in quality of ware after putting this system into use. If there were a change it was probably for a better quality. With this system, there was less hounding of the men to obtain the quality which we ordinarily required. It appeared that the men were more willing to take time to bring up this quality.

There is no doubt that Standard Time will not work in many cases. We have operations such as the casting of large pieces in which one man is casting perhaps one hundred different shapes each day. Some of this work will run beyond the man's work-day period and in this time perhaps two or three men will attend to the filling of the molds, emptying, etc. This means that it would be difficult to determine the time which each man gives to a certain mold.

Another department in which it is difficult to institute an incentive system is the clay preparation department for dry pressing. In this department the men need only to prepare sufficient clay for the dry pressers. They are consequently limited by the amount of pressing which is done or the number of pressers at work. Obviously this overhead for the preparation of a uniform quality of material will vary considerably. At the present time we are preparing this clay by day work. In one dry-press department of my acquaintance, the men were paid in proportion to the aggregate wages of the pressers. This worked fairly well but was not simple in that the men in the clay-preparation department were able to calculate what their wage would be.

It is difficult to put the preparation of clay for saggers on an incentive system unless the whole department is operated as a gang. In a sagger department of my acquaintance the gang was paid a definite amount per hundred saggers delivered in first-class shape to the kiln placers. By so doing, the responsibility for drying as well as the pressing and preparation of the clay was placed in the hands of the gang.

There are certain operations whose times are predetermined, such as ball-milling. The time required for ball-milling a body in porcelain manufacture has been determined by the laboratory, and this of course is beyond any workman's control. Any speeding up of the process must be on operations not so limited. For this reason, as well as the fact that the preparation of the body is really so critical, only day work is used in this department.

The quality of the product is easily determined. The percentage of defective pieces is determined, of course, by the inspection department, which makes a visual inspection as well as electrical tests. The inspection department's tests also include the penetration of organic dye under 50,000 lb. per sq. in. hydraulic pressure. The electrical test, of course, is final and very definitely determines the quality of the ware. It is of course necessary to have competent foremen to maintain eternal vigilence in tracing causes of any defects which might occur. This is obviously necessary in the case of any incentive system which might be used.

As has been stated, it is necessary to have standardized methods of manufacture and standardized methods of determining quality of materials in order that there may be no interruptions or irregularity in the manufacturing process. Under our conditions there is little possibility for the men to complain of slip consistency due to the fact that this is standardized by the control laboratory. A large amount of our work is done by machinery and we do not therefore experience a large amount of trouble by intermittent losses such as are encountered where the production is more largely a matter of craftmanship.

Our inspection department is somewhat independent from our factory, and it therefore feels free to use its own judgment regarding the standards established. Inasmuch as it is independent of the porcelain factory management, the attitude is generally an independent one and consequently establishes a high standard.

# The Control of Quality in a Manufactured Product

By JAMES H. MARKS,[1] DETROIT, MICH.

THE control of quality in a manufactured product can only be accomplished by coordination of design, provision of adequate and proper equipment and tools, establishment of proper controls to keep elements of the product within the limits of the standards set, and—by far the most important—the education of a controlling personnel.

The making of a fine product is the result of carrying out a vision. In order to manufacture an article of high quality by modern industrial methods, it is necessary for this vision to exist in the minds of the management the same as it is necessary for the image of a beautiful picture to be in the mind of the artist. In practice in industry this vision is called the design, so the first requisite is the preparation and development of a design in which the desired quality product is fully detailed and explained. The designer must put the requirements into the design that will bring out a well-balanced, completed product incorporating the high standards which are in his mind.

This interpretation of his wishes must be necessarily done by mechanical means. He must use drawings and specifications to outline what is to be made. The drawings show the outline of each part, what it is to be made of, the accuracy with which it is to be made, and the finish that is to be put upon it. These drawings are further amplified with elaborate and exhaustive specifications describing with utmost detail the quality of materials, and the method and kind of workmanship to be used in accomplishing the degree of finish desired. It is impossible to produce a quality article by modern manufacturing methods without such mechanical methods of interpretation. The designer must not only be capable of creating a fine product in his mind, but he must be capable of interpreting what the product is to be made from and how it is to be made and finished if the desired result is to be obtained.

When the design has been completed it must passed be into the hands of master craftsmen who know how to interpret the work of the designer and how to produce it. The mechanical organization which is to outline the means and methods for accomplishing the vision of the designer must know the machines, tools, and methods necessary and adaptable to accomplish the desired end. Where the workers are skilled only on one machine or even one operation on one machine, it is necessary to have machinery and equipment which is automatically capable of producing work of the desired accuracy without relation to the skill of the workmen. The mechanical organization which prescribes the machinery, tools, and methods to be used in accomplishing the desired result must be fully conversant with all that is available for economically doing work of the desired quality.

The next element in control is a combination of human skill and mechanical equipment. Gages are made to make certain that the work produced falls within the limits prescribed by the designer, and that the machines and tools have done their part in carrying out the plans of the master craftsmen. Any one who has had experience in manufacturing knows how difficult it is to set an absolute standard and work to it. There is no such thing as absolute uniformity. It is therefore necessary to not only have tolerance in limits, but human judgment as well to obtain the desired result. In order, then, to have proper control of quality, an organization must be developed to exercise this judgment and decide not only whether the parts made to enter into the completed product fall within the limits prescribed, but also whether these under certain circumstances are usable in combination with each other. This organization must be composed of experienced, thoroughly competent mechanics.

The sciences of physics and chemistry have amplified the ability of engineers to control the quality of materials. This application of science is usually represented in the modern manufacturing institutions by the mechanical, physical, and chemical laboratory. The functions of this organization and place are to interpret the designer's idea relative to the quality of materials in terms of written specifications; to test out the operation and features of the design, in order to advise the designer as to what he can accomplish; to prescribe methods of operation such as the heat treatment of materials, application of plating, process of painting, and similar others; and to be the check to determine that the quality of materials selected by the designer are used and that the specifications as to degree of finish are carried out. Measuring devices and gages are not enough to insure quality without the use of judgment and the knowledge of science as essential aids.

The most important thing necessary for accomplishment of a high standard of quality is the education of the entire manufacturing personnel to the standards desired, and this of all the things is the hardest to do. It is easy to obtain precision machines and tools and accurate gages, but it is very difficult to develop in the minds of a group of men one and the same thought relative to a standard of workmanship. A plant may have all of the machines and tools and precision instruments that are known today, but not have the ability to turn out a product of high quality. It is therefore necessary to have men of experience who are able to say, without perhaps being able to explain just why, either this thing will go or that thing will not go if the standard of product is to be maintained. This knowledge is a sort of a sense that is developed by years of contact between the master craftsmen and the designer.

The vigilance of this organization can never relax. We all know of cases in which some product has varied from one standard to another from time to time, at one time in its history having been recognized as the par excellence of quality and at some other time having passed to some mediocre place in comparison.

There can be no relation between quality control and production control except that production control, resulting in an uninterrupted flow of materials, makes quality control easier. If an organization sets out to maintain a certain standard of quality and obtain a certain amount of production constantly and at the same time, either one or the other must suffer. If a quality product is to be turned out, quality must come first and uniform rate of production must be secondary. To tolerate the use of improper material for the sake of uniformity of production is absolutely incompatible with quality manufacture. It has been proved again and again that the finest quality of work can be done in quantity production. The reason for this is that large quantities warrant large investments in machines

[1] Purchasing Manager, Packard Motor Car Co. Mem. A.S.M.E.
Presented at the National Meeting of the A.S.M.E. Management Division, Rochester, October 26 and 27, 1927. Slightly abridged.

and tools. The better the machines and tools, the finer the product. It does not necessarily follow that because things are manufactured inexpensively they are manufactured poorly.

The most important factors in accomplishing quality results are engineering as it carries out the design, and a trained personnel as it interprets the design in the finished product. The provision of adequate machines and tools is important but secondary. The ideal comes first, the organization, second, and the means to the end, last.

## Discussion

M. R. Edwards.[2] The smaller factory cannot hope to be able to draw up standard-parts lists, and procedures, and to index and cross-index standard designs for the convenience of the designers and draftsmen. In this respect it must more nearly conform to the older, more entirely human method whereby the designer followed out all the subsequent details of drawing, tracing, checking, etc. The modern trend is to specialize, with one expert to create, another to visualize, another to detail, and a last to fix standards and tolerances. Experience indicates that in the drawing office as in the factory, four experts can produce more than four times as much as one "all-around" man.

Decision whether or not to invest in tools is made in the large factory usually on the recommendation of the engineering force after exhaustive investigation of costs balanced against possible increased quality or production. The manager in the smaller factory, who must largely make his own investigation, must first study his product, bearing in mind that the operations which cost most usually offer the largest chance of savings. He must next thoroughly canvass the machine-tool field to find the best machine for his use. The writer at one time purchased a vertical miller to perform a certain operation and later learned that a new machine called a "nibbler" would have done as good work at one-fourth the investment cost. A complete, up-to-date file of machinery equipment should be at the hand of every such manager. While a manufacturing process is in the stage of transition to a better method (as all processes are doing), what may appear to be an improvement in quality or quantity may in reality be largely due to natural increasing skill on the part of the human element involved, and the new tools may be getting undeserved credit for the improvement.

No manager should economize on gaging and inspection in his drive to improve quality. His gages and precision tools are if anything more important than his manufacturing tools, in view of the modern trend toward the employment of less-skilled mechanics. A thorough, intelligently distributed line of gages will nearly pay for itself in savings of wages made by the possibilities of employing lower-grade inspectors. Experiences during the war bear out this point. The writer believes that in 99 cases out of 100, management is responsible for a poorly executed mechanical product. Every workman, no matter how low in intelligence, possesses some pride in his handiwork. Provide him with proper means and it will show up in the finished product.

Wm. E. Wheaton.[3] The author considers an ideal plant, but the greater number of our plants are not ideal. The management has to visualize the finished product, and not only has to consider the ideal of quality but in addition must consider very carefully the all-important item, cost. This necessarily causes some sacrifice of quality so as to meet competition. Due to our present competition it is necessary to first design an article that will fill the necessary requirements, consistent with the desired quality, in the cheapest way. After arriving at a decision as to the quality of the article to be produced, the writer then agrees with the author when he says that "first of all comes the educating of the controlling personnel." Coordination between the management and engineering department on the one hand, and the operating or producing on the other, is vitally essential. Those responsible for production are the most familiar with the ways and means they have at their command of producing the desired quality.

Our present method of conveying the information as to what is to be produced is by means of drawings and specifications. Let us only consider two schemes, one the drawings and specifications as required in a plant, such as an automobile factory, where they have continuous production, and the other a plant in which heavy machinery is produced which has a variety of sizes but a general standard design. To call for the same limits and specifications on the drawings used in the first shop for the second shop would not be practical nor would it allow of production at a cost that would meet competition. The same would hold good of the drawings used in the second shop, if one were to attempt to use them in the first. In the plant first described there would be frequent inspection, sometimes between each two operations and often during an operation. Gages, jigs, and fixtures would be used, and all modern equipment to produce the quality desired in the least time. While the second plant might have no inspection at all and yet produce an interchangeable product. The writer knows of one plant in which each workman inspects the work done on the operation just previous. All jigging is so arranged that the fit of the jig tool, or fixture depends on the correctness of the previous operation. As to the final operation, this is inspected by the assembly men.

Let us again consider the two plants from the standpoint of their mechanical equipment. Assuming their machine equipment being equal, let us consider their jigs, tools, fixtures, etc. The jigs or tools necessary to manufacture with are those such as drill jigs which produce parts to be fastened together and must be the same. Those used to increase production are such as holding fixtures for milling planing, turning, boring, and shaping, also tooling for automatic and semi- and multi-automatic machines. To secure quality control alone it is not necessary to have both types of tools, but only those necessary to produce. But to secure quality and quantity it is necessary to have both. It may be possible to produce an interchangeable product without either of these classes of jigs or tools, but the cost would be prohibitive.

Plants that do not have laboratories can get along very well as there are laboratories specializing in this work in most manufacturing centers, at which tests can be made or analyses had; and the mills and dealers today invariably supply material as ordered.

It may be true that quality and quantity are not directly related, but they are very closely related indirectly. Quality control can be more easily maintained when there is quantity production, but this does not mean that quality cannot be had apart from quantity production. Quantity can be had with or without quality control, but it seems that in most cases some quality is specified.

What has been said has been with a view of describing the way quality is maintained in a practical way, cost and quantity taken into consideration. The writer also believes that cost is as much a factor in the design or visualization of an article as the ideal.

[2] Mechanical Engineer, Bemis Bros. Bag Co., St. Louis, Mo. Mem. A.S.M.E.

[3] Works Manager, Walter Scott & Co., Plainfield, N. J. Assoc-Mem. A.S.M.E.

A. G. Peter.[4] The determination of tolerances is perhaps one of the most important factors for the control of quality, from the standpoint of the shop man. While it may be possible to fix limits of accuracy in the engineering department when the details of a design are worked out, still the writer believes that in the majority of cases these are the result of actual tryout in the shop during the early stages of production.

In the average plant, tentative tolerances are determined by the designer or the shop foreman, based on experience; and as tools and jigs are completed they are tried out on small lots, working to these limits. Eventually all of the parts are on hand and assembly begins. Then as difficulties arise, either in fitting the pieces together or in their subsequent operation on the test floor, these are noted and dimensions are adjusted accordingly. Through the early stages of production a constant changing of sizes goes on, until finally a point is reached where every part seems to be just right, which then becomes the standard of manufacture. These changes are all infinitesimal, often involving amounts measurable only with the finest of precision instruments, and in no wise involve the design. Nevertheless they have a tremendous effect in transforming the vision of the designer into a practical reality.

Manufacturing costs as well as the perfection of the finished article depend largely on the degree of precision required in making the component parts. Unnecessarily stringent demands of accuracy or finish add very little to the mechanical value of a product, and they may raise the cost beyond the point where it is salable. This must always be borne in mind: Quality should be maintained up to the point where it is consistent with the demands of the product as a practical and salable mechanism. Anything beyond this means money wasted in increased costs. Of course the determination of what is practical depends entirely on the function of the product, and on the market for which it is intended.

# The Apprenticeship-Training Program of the Tri-City Manufacturers

By S. M. BRAH,[1] MOLINE, ILL.

THIS paper will treat the subject in three principal sections: first, a description of the community problem; secondly, an explanation of the system of apprenticeship training; thirdly, the results of the training under this system.

A community training program is of itself a complex problem. Whether the community be of large or small size matters little, for there are many minds that must agree on the basic principles of the training program as to policies of work schedules, rates of pay, and school or classroom work, or material to be used. After this particular community is outlined, a better idea will be gained of the need for unity in thought and action to make such a program a success.

The community under discussion is commonly known in the industrial world as the Tri-Cities, and includes the cities of Moline, East Moline, and Rock Island in the State of Illinois, and Davenport and Bettendorf in Iowa. These five cities located in two states have a total of forty-one companies, varying in size from 30 employees, in the smallest, to 1200 in the largest plant. Seven trades are included in varied types of shops and, almost without exception, a different degree of skill is required by each concern. Farm implements and accessories predominate in the list of articles manufactured, which includes laundry equipment, gas engines, electrical household appliances, harness, hardware, automobiles, railroad cars, scientific apparatus, elevators, jobbing castings, industrial locomotives, and pumps. Thus it can be seen that a variety of establishments participate in this program. The communities have much in common in every way, except politically. Residents in one city may work in another, shop in a third, and go to the fourth for their recreation. Each city has its own school system. The interests of all the industries are centered in one organization known as the Tri-City Manufacturers' Association, and it was under its sponsorship that the system of apprenticeship training herein described was inaugurated.

An expert staff was called upon to install a working program in the Tri-Cities. A personnel entered the field and made a survey as to the type of apprentices needed in the community and the number required for all purposes. This entailed a survey of 41 plants where metal-working operations were carried on. The number of employees was tabulated, various operations noted, statistics of turnover studied, and a report issued for each individual plant. The sum total of these surveys was analyzed and summarized and a brief was submitted to the Board of the Manufacturers' Association. The brief included the number of apprentices required in each trade and in each shop. The courses of instruction, rates of pay, schedules of work, and indenture forms were submitted to the Board and were accepted. It was then suggested by the personnel that a committee be formed and charged with the duty of carrying on the necessary administrative work. The manufacturers of each community were appointed as a body to present the problem to the schools for assistance in the way of classrooms and teachers. The response came whole-heartedly. For the first year or two it was decided that the schools in Illinois would be grouped under one teacher who would conduct the classes in each community as needed. The same idea was carried out in Iowa. After the plan was agreed upon by all school districts involved, the project was brought to the attention of the State Vocational Departments for aid from the Smith-Hughes fund. Their assurance of aid added zest to the work in hand and the problem of getting the apprentices was attacked.

A publicity program was planned to include talks to the graduating classes of all the schools, to parent-teachers associations, to clubs, and to civic organizations. An appeal was made to parents through the newspapers, showing the opportunities to be had in the trades in their own community. The initial response was not gratifying. However, the pessimism of many could be overcome by showing them as an example an apprenticeship program that had been going on for years right in the community; namely, that carried on at the Rock Island Railroad Shops at Silvis, Ill., which had been successfully training apprentices for the past 13 years.

Arrangements were made to interview the prospects with their parents or guardians and the plan was explained to them in full. A sufficient number were interested to make it possible to start and the first apprentice under this plan entered the employ of a foundry in Moline, April 28, 1926.

### System of Training

The so-called "system of training" so often spoken of is nothing other than work for the apprentice; the big factor being that he is actually given the work and not just promised it. It is the duty of the district supervisor to see that each apprentice is given the training called for on his indenture. It is also his duty to see that each apprentice attends school regularly and receives an increase in pay at the proper time.

Each apprentice is given an indenture wherein the schedule of work is outlined. For the machine-shop apprentice, this consists of the following operations:

| Schedule of work | Hours |
|---|---|
| Tool crib | 250 |
| Drill press | 400 |
| Screw machine | 400 |
| Shaper | 450 |
| Planer | 450 |
| Milling machine | 450 |
| Small tools | 150 |
| Engine lathes | 1800 |
| Turret lathes | 1200 |
| Boring mill and bar | 1200 |
| Grinders | 700 |
| Erecting and assembly | 950 |
| Special work (experimental room, drafting, etc.) | 1360 |
| Total | 9760 |

The total is based on 208 weeks of 47 hours each, or a period of four years.

The time distribution of the work schedule is varied to meet the needs of the shop and its equipment. The schedule serves as a guide for the shop supervisor or foreman in making out the indenture for his apprentice. A schedule of the rates of pay is included. The starting rate is twenty cents with a three-cent increase every six months.

The policy of having supervisors for each shop (that is, someone whose sole duty it is to instruct the apprentice) has not been

[1] Apprentice Supervisor, Tri-City Manufacturers' Association, Moline, Ill.

Contributed by the Committee on Education and Training for the Industries and presented at the Summer Meeting, St. Paul-Minneapolis, Minn., August 27 to 30, 1928, of The American Society of Mechanical Engineers.

carried out except in a few cases. The experience is that it will pay to do this but there has been a tendency on the part of the plants to do without the services of this man. In most cases, the foremen have taken the apprentices under their immediate care and have seen to their shop instruction. While this practice has been criticized by many, it is felt that since the training of apprentices is the object, the best training available is desirable as well as creditable. Whether or not the foreman is a capable instructor for apprentices is debatable, but the writer feels that if he is capable of training all others in his department, he certainly can train the apprentices. Usually, the criticism comes from those who are *not* training apprentices, and the writer wonders who is the greater sinner. One thing is certain: where an apprentice supervisor is maintained by the plant, a spirit of apprenticeship is built up in the minds of the foremen and the apprentices themselves sooner than when one is not employed. Upon this the success of a program depends.

A record of the apprentice's time and the work he has done is kept by the time-keeping department which turns in a monthly report to the district supervisor, so that he may enter this information on a control chart. A section of the control chart is shown in Fig. 1.

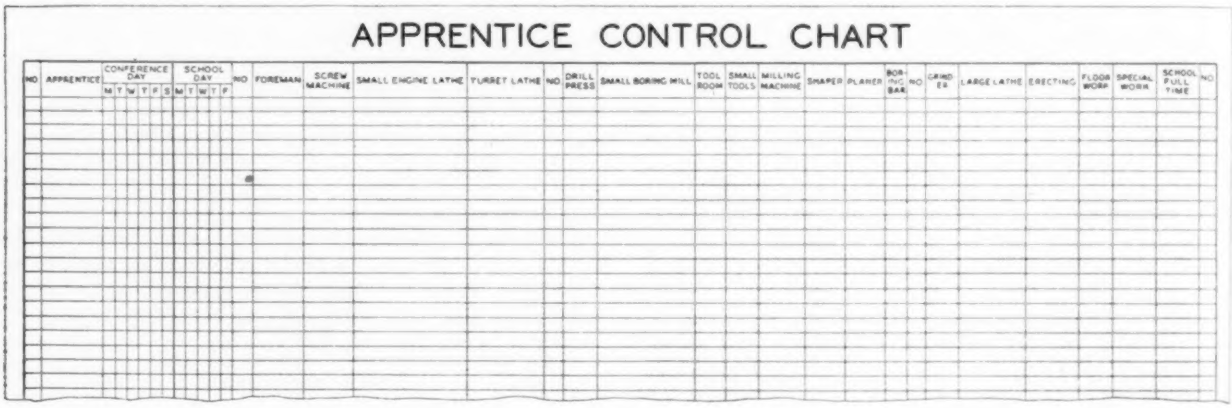

Fig. 1

(Small divisions under job headings indicate a definite number of hours. In the original, 200 hours are represented by each quarter-inch division.)

The information it contains is summarized as follows: The operations the apprentice has served on, the length of time spent on each, and the one engaged on at the moment (this latter by the use of a map tack). The shop has no other records to keep. It was felt that if the records were minimized, the foremen would take more interest in the program as a whole, for in many cases, worthy causes have died by the wayside because of their burden of records.

### Duties of the District Supervisor

The district supervisor's duties may be summed up as follows:

1 Plant surveys
2 Sell the management and personnel on apprenticeship
3 Interview and classify applicants
4 Act as mediator between apprentice, parents, and the shop
5 Maintain records as to changes of rate or work
6 Promote interest in the community by talks and written articles
7 Plan outside activities for the apprentices
8 Be ready to assist the plants, committees, school instructors, or apprentices on any matter on which he or they desire counsel.

### School Work

Correspondence courses have been provided as classroom-instruction material. A carefully selected list of subjects is chosen from the engineering and business courses. The courses contain mathematics, science, drawing, and related work (that is, texts on information relative to the machines and the processes involved in that particular trade). An outline of the text material in the machinist course is as follows:

*Mathematics.* Elements of arithmetic, fractions, decimals, ratio and proportion, weights and measure, powers and roots, mensuration, use of trigonometric tables (the high-school graduate is not required to take this work if he can pass a satisfactory examination), algebra, logarithms, slide rule, and geometry.

*Science.* Shop economics, measuring instruments, precision measuring instruments, mechanical principles, hardening and tempering, and heat treatments of low-carbon steel.

*Drawing.* Geometric and mechanical drawing (nine plates of the familiar geometric figures and their projections, and eight plates of various machine elements) and sketching in perspective and planes.

*Related Work.* Lathe work, drilling, milling machines, shaper and slotter, planer work, boring mills, gear calculations, gear cutting, grinding, and bench vise and floor work.

*English.* Capitalization and punctuation, letter writing, and English composition.

Each apprentice is enrolled in a course upon completing his probationary period (three months).

The classes are held in the local public schools. A regular recitation room is used, fitted with blackboards and drawing tables. The school board of each community furnishes this as well as the instructor. In Iowa, the instructor is one of the manual-arts-department men who gives part of his time to this work. In Illinois, the three communities have engaged one man to act as instructor in all three cities and the expense is prorated. The communities are later reimbursed to the extent of 50 per cent by the State Department of Vocational Education through Smith-Hughes funds available for such purposes.

The student attends class four hours per week in one period. He is expected to spend an equal amount of time in home study. A minimum requirement is set up and all apprentices are expected to meet it. The apprentice's time in the class is divided between mathematics, drawing, and related work in such proportions that his interest will not lag. The instructor selects the text to be studied and assigns the amount that the apprentice must work upon for the next class period. The text selected usually corresponds with the operation on which he is working in the shop. When he has completed the material he changes to a text related to the process on which he will be placed next.

The reason for this type of instruction material and procedure is self-evident to any one who has tried to instruct apprentice classes. The advantages are pointed out in the following:

1 Elimination of the necessity to review texts and authors to obtain a proper and related course
2 Elimination of the detail work—correction of lessons and lesson preparing
3 Home-study courses such as these can readily be studied at home and require the minimum of help from the instructor in the class
4 Each student can proceed at his own rate according to his mental capacity
5 Each student proceeds along the line in which he is most interested, whether it be the machinist, electrical, or some other trade
6 Grade- and high-school students as well as newly indentured and advanced students can be accommodated in the same class, keeping the number of classes to a minimum.

The cost of the courses is $100, payable at the rate of two dollars per month. If the amount is paid in cash, the price is $75. In the Tri-Cities this cost is borne jointly by the apprentice and the employing company.

### Cost of Apprentice Training

Nothing definite can be given on the cost of training apprentices, as many items vary over a period of a year. However, the following will show the cost for one year in the Tri-Cities:

| Item | Plant | Apprentice | School and Assoc. |
|---|---|---|---|
| Wages per year, average | $750.00 | | |
| Course | 12.50 | 12.50 | |
| Instruction and supervision | | | 40.00 |
| Miscellaneous (banquets, contests, activities, etc.) | | | 3.00 |
| Total cost per year for each party concerned | $762.50 | 12.50 | 43.00 |
| Grand total | | | $818.00 |
| Wages and expenses for each apprentice at school | | | $ 58.56 |
| All other expenses per apprentice | | | 68.00 |
| Non-productive expense | | | 126.56 |
| Productive labor expense | | | 691.44 |
| Total | | | $818.00 |

The above amounts are computed as follows:

The boy attends school four hours per week for 48 weeks per year—

$4 \times 48 = 192$ hours per year.

Minimum rates, 20 cents per hour; maximum rate, 41 cents—

$20 + 41 \div 2 = 0.305$ dollar.

| | |
|---|---|
| Amount paid boy by shop for time spent in school, $192 \times 0.305$ = | $58.56 |
| Cost of correspondence material, borne by boy | 12.50 |
| Cost of correspondence material, borne by shop | 12.50 |
| Salary of teachers, supervisor, funds for banquets, prizes for contests, etc. | 43.00 |
| Total overhead charges | $126.56 |

A total of $691.44 is paid for time spent in the shop.

### Results

The program herein described has been in operation less than three years and it is impossible to point to any number of apprentices that have finished their trade entirely under the program. However, it is felt that some measure of the success of the program may be gained from the following figures:

| Number of apprentices | End of first year | End of second year |
|---|---|---|
| At work in all shops | 84 | 125 |
| Attending classes | 60 | 119 |
| Number estimated in the survey | 125 | 250 |
| Maximum number called for in survey | | 425 |

| Applicants on file | End of first year | Second year | Apprentices at work second year |
|---|---|---|---|
| Machinist | 50 | 125 | 55 |
| Foundry | 48 | 60 | 28 |
| Pattern shop | 8 | 24 | 21 |
| Electrical | 5 | 30 | 3 |
| Plumbing and pipe fitting | 4 | 8 | 1 |
| Drafting | 8 | 23 | 0 |
| Sheet metal | 2 | 1 | 2 |
| Printing | 1 | 9 | 0 |
| Office | 2 | 6 | 4 |
| Manufacturing | 1 | 3 | 5 |
| Wood working | 2 | 20 | 0 |
| Unclassified | 14 | 11 | 6 |
| Total | 145 | 320 | 125 |

Examination shows that a large percentage of the applicants are not placed. This is due to no one particular cause. It has been deemed wise to go slowly and not overburden the shops with apprentices at the start. It must be remembered that the foremen are acting as supervisors of the apprentice as well as foremen in the department, and to burden them too heavily would be a mistake.

Applications on file, classified as to educational qualifications of the applicants, are as follows:

| | |
|---|---|
| Number completed grade school | 83 |
| Number completed first year high school | 80 |
| Number completed second year high school | 37 |
| Number completed third year high school | 13 |
| Number completed high school[2] | 107 |
| Total | 320 |

No applicants are accepted unless they have completed the eighth grade.

### Turnover

Tables of turnover showing the number lost in various trades during the first and second years, the trade in which the apprentice was indentured, and the reason for the turnover are tabulated as follows:

Turnover

| Cause | First Year Mach. shop | First Year Foundry | First Year Pattern shop | Second Year Mach. shop | Second Year Foundry | Second Year Pattern shop |
|---|---|---|---|---|---|---|
| Quit | 2 | 9 | | 1 | 7 | |
| Lack of interest | 5 | 1 | | 0 | 0 | |
| Lack of ability | 3 | 1 | 2 | | 1 | |
| Discipline | 3 | 1 | 1 | | | |
| Transfer | | | | | | 2 |

Total turnover, 37, or, based on percentage of total number apprentices at the time, 30 per cent.

Average monthly turnover for two years, 1.25 per cent.

Turnover School vs. Shop Fatality

| Cause | First Year Mach. shop | First Year Foundry | First Year Pattern shop | Second Year Mach. shop | Second Year Foundry | Second Year Pattern shop |
|---|---|---|---|---|---|---|
| Inability to master school work | 2 | 1 | 0 | 0 | 1 | 0 |
| Inability to master shop work | 6 | 2 | 0 | 0 | 0 | 0 |

General Summary

| Item | First year | Second year |
|---|---|---|
| Number of plants employing apprentices | 17 | 21 |
| Minimum number of apprentices in any plant | 1 | 1 |
| Maximum number of apprentices in any plant | 12 | 13 |
| Number of plants with one apprentice | 3 | 2 |
| Number of plants with two apprentices | 3 | 2 |
| Number of plants with three apprentices | 2 | 4 |
| Number of plants with four apprentices | 3 | 4 |
| Number of plants with five to nine apprentices | 3 | 5 |
| Number of plants with ten to thirteen apprentices | 3 | 4 |
| Total number apprentices at work | 84 | 125 |
| Plants dropping out | 0 | |

If these figures are a criterion of success, they are offered for their worth.

[2] Many applications have been filed, but applicants are not available as they have gone to college, or accepted some other position.

The success of this program is due in no small measure to the work of the executives that have served on the committee. Their duties have been many and complex. This committee is made up of five executives from each of the five cities involved, together with the secretary of the Association, and the apprentice supervisor. The committee passes on all matters of policy; acts as advisor to the supervisor; maintains contact with such outside agencies as the schools and state, conferring with them when necessary, acting for the manufacturers as a whole. They act as final agents in securing the cooperation of plants not yet participating in the program.

The committee is the keystone upon which the success of a community project depends, and in this case theirs is the glory of success.

## Discussion

Harold S. Falk.[2] The Tri-City manufacturers are to be highly commended for appreciating the importance of apprenticeship training and for the progress which they have made in the work. It is remarkable how few manufacturers are willing to undertake the training of apprentices although all of them realize that men are the most important element in industry. In spite of the attention which has been devoted to apprenticeship in recent years, the fact remains that, as a rule, only individual manufacturers have established apprenticeship.

But from the very nature of our American industrial organization, apprenticeship can hardly be expected to succeed in the individual plant and the Tri-City manufacturers are also to be commended for having made of their apprentice work a community enterprise and responsibility. Apprenticeship in the individual plant cannot be expected to succeed because the manufacturer who undertakes the training of apprentices without the cooperation of others will soon find that he is supplying mechanics for all the shops in the neighborhood and the burden is so unequal and so unfair that the training is very often soon abandoned. Apprentice training must be made a community responsibility, as we have often explained, with every plant in the district or neighborhood assuming its proper share of the burden of training the quota of mechanics for the district.

Manufacturers have associated themselves for research, for advertising, and for many other purposes. It is high time that they associate for the training of the men upon whom they must depend for the operation of their plants and their business. That such association is possible and profitable has been demonstrated by the manufacturers of the Tri-Cities.

In fact, it may be said that the association of manufacturers for the training of apprentices can be accomplished anywhere at all after the Tri-City Manufacturers have demonstrated its possibility in their case. I say this because it appears to me that the organization in the Tri-Cities has been brought about in the face of very unusual difficulties. A manufacturing community is usually confined to a single city in a single state and the establishment of apprenticeship involves arrangements with only one group of civic agencies, one school system, one city government, and one state apprentice law, if such has been enacted. The Tri-City industries are located in five different cities and these five cities are in two states, and if the organization of manufacturers for apprentice training is possible in such a confusion of municipal and state administrations, it ought to be possible under any circumstances whatever.

It is interesting to note that, in spite of their peculiar difficulties, the methods used by the Tri-City manufacturers have been little different from the methods used in other centers for the organization of apprentice training. These methods, with suitable adjustments for local conditions, should be successful everywhere. In the first place they have given their work publicity in the community as was explained. Experience has shown that apprenticeship cannot be made a success in the plant alone. The undertaking must have the cooperation of the people in the community, of the parents, teachers, and civic organizations. The people must believe in apprenticeship and must see in it an advantage for their sons.

Again, the Tri-City manufacturers found that a committee of executives for the direction of apprenticeship is essential for successful community apprenticeship. Unless such a committee exists, there will be discrepancies in training periods, contract arrangements, schedules of work and pay, and other important features of apprenticeship in the various plants, and serious differences of the kind will destroy the unity of the plan.

Arrangements with local school authorities for theoretical instruction of apprentices is indispensable in a community project for the reason that the small plant cannot afford to maintain a school of its own and the large plant will find it more profitable to utilize the public institutions than to maintain a teaching organization. The work of the Tri-City manufacturers in bringing about cooperation between themselves and five separate school systems in addition to the vocational education departments of two states appears to be quite remarkable and shows what may be done when enthusiasm and determination are applied.

The author makes the statement that apprentice supervisors are not employed in the individual shops and that in most cases foremen have assumed the care of the apprentices. He goes on to state, "Whether or not the foreman is a capable instructor for apprentices is debatable, but the writer feels that if he is capable of training all others in his department he certainly can train the apprentices." The instruction of apprentices does depend upon the foremen and, except for special shop instructors, no better teachers of practical work than the foremen can be found.

However, a distinction must be made between apprentice instruction and apprentice supervision, although the two functions may be combined in one person. Apprentice instruction means teaching the apprentice the various operations which are a part of the training course. Apprentice supervision involves the planning of courses, the maintenance of school and other outside contacts, the selection of boys for apprentice training, the transfer of apprentices from one department or operation to another, the solution of personal problems of the apprentices, and so forth. For this work the foreman is not qualified because he has neither the time nor the opportunity to do it, however well he may be able to instruct the apprentices. Therefore, apprentice supervision must be provided in addition to the instruction given by the foreman. Undoubtedly, this supervision is very well taken care of in the Tri-Cities by the district supervisor. Since there are 125 apprentices in the district according to the latest report, it is still possible for the district supervisor to maintain personal contact with all of them. However, experience indicates that this is about the limit for one man, and if additional apprentices are engaged in the district it will be necessary to put on an assistant supervisor for the district or an apprentice supervisor in one or the other of the larger manufacturing establishments. Apprentices need a person who devotes all his attention to their welfare and to whom they can bring their problems, just as a dean of men and of women and personal advisors are necessary in a university in addition to the professors and instructors.

Finally, it would be interesting to know the basis of the survey of the Tri-City district for the determination of the proper quota of apprentices. There is some disagreement as to the

[2] Vice-President, Falk Corporation, Milwaukee, Wis. Mem. A.S.M.E.

method of establishing the quota. To fix the number of apprentices arbitrarily as one-tenth of the total employment or one-fifth of the skilled mechanics is not satisfactory. Some authorities maintain that the number of apprentices should be determined by the requirement of the district from year to year. Others maintain that the facilities for training in the shops should determine the number. It would be interesting to know how the quota for the Tri-Cities was determined, although we all appreciate that it was impossible to include a full description of the method in a short paper already crowded with pertinent information.

Harold W. Fitch.[3] After reading the paper the writer wishes to express his appreciation of the excellent manner in which a complex problem has been handled. It is no easy task to organize and coordinate the efforts of a considerable number of conflicting interests and Mr. Brah and the board of the Tri-City Manufacturers Association are to be commended on their achievement.

While it is obvious that the program described was designed to meet a local condition, there are three points which are of primary importance as applicable to any system of apprentice training.

1 The author states, "The 'system of training' so often spoken of is nothing other than work for the apprentice—etc." Unfortunately, what is so often referred to as a "system of training" is nothing of the sort but, rather, a lack of system, the apprentice being turned over to a foreman who places the boy where he will least inconvenience him. By observation or the method of "trial and error" the boy may eventually attain some degree of proficiency. When the apprentice feels that he should be transferred to other work it may even be necessary for him to make such a nuisance of himself that the foreman is glad to be rid of him. This, obviously, is not a system of training but, rather, the results of the lack thereof.

Any "system of training" should provide a printed outline showing the time to be spent on each machine or operation as well as the logical sequence of items. It must also provide a means of keeping a record of the performance of each boy on the various operations. (This point was not touched upon in the paper, but it is assumed that provision has been made to keep such records.)

2 As a former foreman the writer wishes to take issue with the statement that the foreman should train the apprentices. The author states, "If the foreman is capable of training all others in his department, he certainly can train apprentices." The writer contends that, with an apprentice training system functioning properly, the foreman has little necessity for training the men who are graduates of such a system. They will have been trained as apprentices and therefore do not need a considerable amount of further training.

Because of the multiplicity of his other duties, and principally because of the fact that production is the primary object of his department, the foreman will all too often sacrifice training for production. We have tried to have foreman instruct apprentices, but the results have not been satisfactory.

3 Apprentice instructors, even though they may travel from shop to shop supervising and instructing the apprentices, have proved to be of great value on the New Haven. Owing to our having over 200 apprentices scattered among a dozen shops and engine-houses, it has been necessary to utilize traveling instructors while also relying, to a certain extent, on the foreman to carry on the training in the absence of the instructor. It is our observation that where instructors can devote their full time to one point the best results are obtained.

[3] Assistant Engineer, N.Y.N.H.&H.R.R., New Haven, Conn. Jun. A.S.M.E.

C. A. Prosser.[4] The writer has been watching the apprenticeship situation for some fifteen years. Dunwoody Institute is engaged in training apprentices for three railroad systems, and from this experience certain conclusions have been reached, right or wrong.

Apprenticeship of the old type is almost disappearing. The writer's experience leads him to believe that this is a day for practical experiments; we have too much talking and not enough action. Many schemes will have to be tried because there are many conditions to meet.

The Tri-City scheme is a real experiment and in many of its aspects it is wisely conceived. It must be watched to determine just exactly the conditions for which it is fitted, what are its weak points, what are the failures, and what are the points of success.

There are many organization features of the scheme that are admirable. The employers of these cities have pooled their activities and have assumed certain responsibility for the youth of the community. They have set up a scheme of cooperation with the public school system. They have attacked the exploitation of the apprentice on the job by setting down on paper the amount of experience he must acquire during his apprenticeship.

The scheme may be questioned on its instructional side. Because a man is a foreman he is not necessarily a good trainer of apprentices. Teaching is as much a trade as foremanship. Ten out of every eleven hours of an apprentice's time is spent in the shop, and the foreman either makes him, leaves him indifferent, or wrecks him. If ten hours of poor training is supplemented by one hour of good training, little good can be accomplished. In a check-up of foremen in the printing trades to learn the methods of breaking in green men, fifteen men replied and outlined eight different methods. They cannot all be right.

The writer does not agree with the plan of having a correspondence course of study taught by local schools, as it is taught in this scheme, nor does he believe that a manual-training instructor is qualified to teach such a course. He challenges the teachings of abstract mathematics to boys in training as apprentices to a trade. The habit of using mathematics involves two things, one, analysis of the situation, and the other, the application to that situation of a formula. In investigations of the use of higher algebra and abstract geometry by tradesmen, the writer has never seen a mechanic who could say what methods he used. It may be that there are engineers who bring to bear in their daily work a knowledge of basic algebra and geometry, but this is not true in the trades. A mechanic analyzes the problem he has to meet in the shop and decides which formula applies. He has to be a master of the use of that formula before he solves the problem. Too many times engineers assume that a knowledge of higher algebra and geometry is necessary for the solution of a job by a mechanic when this is absolutely not true.

The writer believes that it is a waste of time to teach abstract algebra and geometry to boys in high school. The writer also believes that the way to teach a boy to read blueprints is to teach him to read blueprints. Such a course as the one offered at the Tri-City school is an attempt to make draftsmen. If we are making mechanics we should teach them the trade in so far as it applies to the work a mechanic has to do. Let him take additional training later if he has an ambition to become a draftsman.

The author points out that a correspondence-school instruction course is used because it supplements the weaknesses in the teaching force. No correspondence-school course of instruction will ever take the place of the living teacher in the class. There are exceptional men of high ability and long experience who never do well in a class and who get a lot out of a home-study course. The correspondence school has a definite place in American life,

[4] Director, Dunwoody Institute, Minneapolis, Minn.

but in the opinion of the writer it has no place in teaching a trade to unskilled and inexperienced boys by absent treatment through a teacher unfamiliar with the trades taught.

In the end the employer pays the bill. With a cheap scheme he saves money at the spigot and wastes it at the bung. If the overhead is reduced, the employer pays for it in the poorly prepared apprentices. If he lets the community do it and pays the tax, he meets the burden. If he sets up a scheme that costs more money but is more efficient, he pays the cost but reaps the better results.

R. K. Erskine.[5] We are not so much concerned with highly skilled mechanics as we are with leaders of men, men able to cooperate with other men, and good instructors. What we demand in our business is highly skilled foremen, good instructors, and good set-up men. Two years ago we established a course and had one man from the Extension Division of the University over twice a week for evening sessions. Instead of getting new men and starting them in as apprentices, we selected a group of men from our own works-foremen, and prospective foremen—men who we thought would develop. These men were trained for the job for which they were best suited. If a man shows ability in cooperating with the other men, we may figure that he will make a good instructor, and that he is well fitted as a foreman.

What we demand of a foreman or instructor is leadership, ability to cooperate, as our work passes from department to department, the schedules depending on how foremen realize the problem. We demand good instructors. Our business is reasonable and we have to take on new men, train them, and probably lose most of them after a period of five or six months. Then we demand a good basic understanding of the trade. Some foremen have taken advantage of the trade schools in Minneapolis and it is interesting to hear a paper such as this because in our own case we are looking for just such things. We appreciate the work that is being done.

P. S. Van Wyck.[6] The writer stated that instead of teaching men as draftsmen, blueprint reading and shop sketching should be emphasized, the sketches to be suitable to work from in the shop. The writer questioned the use of obsolete correspondence-school tests, favoring up-to-date textbooks in preference, but agreed that newly revised correspondence-school texts would be equally acceptable. He preferred to use job sheets with the tests as references, for his own part.

Luther D. Burlingame.[7] The Brown & Sharpe Manufacturing Co. has had an apprenticeship system for sixty years which it is interesting to compare with one just started. The Brown & Sharpe apprenticeship system is sufficient unto itself because there are nearly two hundred apprentices in this one factory. In developing skilled workers we are also cooperating with other manufacturing plants in Providence and vicinity in carrying through a cooperative scheme which we believe can be adopted in any city.

It is interesting that a foreman very often does not want an apprentice, and that in the Tri-Cities this attitude has been changed so that foremen welcome apprentices. The grinding and gear-cutting departments of the Brown & Sharpe Co. were considered outside of the regular apprenticeship courses and apprentices did not go into them. When it was decided that apprentices should receive instruction in these departments, the foremen "threw up their hands" and said that they could not be bothered. However, they were persuaded to try the scheme, and one of the boys first selected to go into the gear department did so well that the foreman not only wanted him but asked to retain him for a longer period than had been planned as he had some important work he wanted him to do. Actual contact changed the feeling on the part of the foremen and they no longer objected to apprentices in such special departments. They had thought of the boys as just starting in, whereas they were two or three years along in the course when they came to these departments and had matured to a point where their training was worth while.

The thought has been expressed that the old apprenticeship system has passed away. Instead it has developed into the modern system which is far more efficient and gives much better training. In our training, certain boys show an aptitude and express a desire in the fourth year for foremanship and they are trained for and developed into foremen. Under the present system of apprenticeship the boy is getting a far better chance than the apprentice formerly did.

C. J. Freund.[8] In discussing foremen's qualifications for teaching apprentices, a distinction should be made between qualifications for teaching the practical side of apprenticeship—operation of machines, grinding of tools, etc.—in the shop and qualifications for teaching related trade subjects, mathematics, etc. Certainly, as has been pointed out, the foreman is seldom an ideal instructor; undoubtedly a professional teacher is much better. However, only the largest plants can afford full-time professional teachers in the shop.

Several years ago in Milwaukee, manufacturers built up a considerable fund to build a trade school which could accommodate about 400 boys at many different trades. The school has since failed as a private enterprise and has become a city trade high school. The reason for the failure was that it was soon discovered that although there was a great amount of special equipment, large building, etc., it was impossible to train the number of mechanics required in the district.

There are now in Milwaukee about 950 apprentices in the machinery-building trades. The investment in a trade school which would be required to teach 1000 boys in machinery building alone, not to mention leather working, food industries, etc., would be so large as to be impracticable. This forces the employer to utilize the foreman as an instructor of apprentices on the machinery in the shop, and this is a more feasible plan, regardless of the foreman's limitations than a limited amount of equipment and a limited number of boys in a trade school, in spite of the better trained and more efficient teachers. Of course, the plan does not prevent the apprentice from spending part time in a school with professional teachers who teach him related trade technique and as much actual machine operation as time will permit.

There is another thing which the apprentice gets from the foreman which he cannot get from anybody else, and that is a proper attitude toward production. In the case of an apprentice, training is the first consideration and production is secondary but the apprentice is apt to interpret this as meaning that training is everything and production is nothing.

He would willingly spend a day or a week on one small piece in a lathe if he were not working under a foreman, but the foreman is pressed by the management for production while he is training the boy, and therefore he will teach him better than any one else can how to get out his work, how to save time, how to be

[6] Department Head, Machine Shop, Dunwoody Institute, Minneapolis, Minn. Assoc-Mem. A.S.M.E.

[7] Industrial Superintendent, Brown & Sharpe Mfg. Co., Providence, R. I. Mem. A.S.M.E.

[8] Apprentice Supervisor, Falk Corporation, Milwaukee, Wis.

efficient, so that when the boy finishes his apprenticeship he becomes a real factor in production.

A distinction must be made also between the instruction and supervision of apprentices. In the ordinary plant, foremen must be instructors of apprentices but they have not the time to be supervisors.

## Author's Closure

In reply to Harold S. Falk's discussion: an assistant district supervisor has not been added, but in place, whenever a shop has more than ten apprentices, some individual has been appointed acting supervisor for that plant.

In reply to Harold S. Fitch's discussion: confusion, no doubt, resulted from the paper in the statement that no system of training was used in the Tri-Cities and later the schedule of work was included. If a printed schedule of work may be considered system, there is one in use in the Tri-Cities. Mr. Fitch does not seem to understand that the foreman is the only one provided by the management to train the apprentice. A misunderstanding must have resulted as no apprentice instructors exist for shop work. They are concerned only with the class work which is carried on in the local schools.

In reply to Doctor Prosser's discussion, as to the desirability of foremen as instructors: the author merely states that foremen are capable to instruct and this method was resorted to inasmuch as teacher trainers were too expensive for companies having five or less apprentices. No two educators would agree on what mathematics is most desirable for vocational work, but all are willing to agree that the fundamentals must be firmly established before future work can be attempted. That is what has been done in the Tri-Cities. The vocational mathematics is included in the text of related work. No better material has been offered than correspondence-school text and all weaknesses are being overcome by classroom supervision.

The Doctor's contact with manual training teachers has surely taught him that there are men of *all* calibers in this field and we feel that ours is of the *higher* caliber, fitting him for the task at hand.

Replying to P. S. Van Wyck: inasmuch as sketches are seldom used in production shops, actual line drawing is taught to familiarize the apprentices with drawings so that they may read blueprints intelligently, accurately, as well as quickly.

The correspondence-school test material is revised regularly and in some instances, yearly, and is more recent than any other type of text material available.

The author is in perfect accord with what Mr. Burlingame had to say.

C. J. Freund has answered Doctor Prosser's argument on the foreman's qualifications as a teacher of apprentices. The author wishes to say that the foreman does not act as instructor in teaching classroom subjects. Nor does he act as supervisor. The classroom work is done in the public schools and the supervision is taken care of by a director indirectly employed by the cooperating company.

# An Industrial-Plant-Location Study

## Results of an Analysis Illustrating the Factors to Be Considered in Locating a Plant

By EMMETT B. CARTER,[1] NEW YORK, N. Y.

THE FACTORS to be considered in locating the plant which has been taken as an example in this study include:

1 Trade possibilities for expansion
2 Low distribution costs and speedy delivery
3 Cost and quality of raw material
4 The first cost of the plant and the resulting overhead costs
5 The cost and quality of labor.

### Trade Possibilities for Expansion

The owner of the plant had decided to build a plant to produce 100 tons per day. He had been influenced in this decision by his ability to sell that output and his ability to raise enough money to build such a plant, but for an engineering analysis of plant location more information was necessary. For example, the following questions come to mind:

1 How much land is required for future development? To answer this question a general survey of the trade is necessary.

2 Might this plant eventually be called upon to supply several times the capacity at present assumed? Government reports are of great value in determining the possible magnitude of the industry and its probable growth.

3 With a knowledge of the present distribution of the product the factor governing distribution must be decided upon. Is it population, per capita wealth, climate, or some other factor?

4 Is the geographic distribution likely to remain about as it is now? If not, what change is likely to occur?

### The Cost of Distribution

Having completed a study of the potential market, definite quantities were used for sales forecasts, and maps and charts were prepared to visualize the situation, especially the sales distribution by states, more clearly. This is followed by a complete tabulation of distribution points and probable shipments to these points.

From the maps of sales distribution and a knowledge of freight rates it was seen that a good distributing point lay somewhere in the state of Pennsylvania. However the industry which is considered in the present analysis receives the bulk of its raw material from Europe and full cargo steamers should be able to unload directly into the plant; and therefore with the state of Pennsylvania in mind as a good distribution point, New York, Philadelphia, and Baltimore appeared to be possible locations.

A further study of the raw material, however, disclosed the fact that one ingredient of which considerable tonnage is necessary should be purchased in New Hampshire; hence the New England ports had to be considered. This widened the possibilities so that the Atlantic Coast ports from Boston to Norfolk had to be considered.

### Freight Rates

A tabulation of comparative freight costs from the locations considered was then made as is indicated in Table 1, in which are included only enough destinations to illustrate the method used.

TABLE 1 COMPARATIVE COST OF FREIGHT ON FINISHED PRODUCT TO CONSUMER

| | | Freight costs in dollars when shipped from | | | | | |
|---|---|---|---|---|---|---|---|
| Destination | Tonnage | Boston | New London | New York | Wilmington | Baltimore | Norfolk |
| Ashtabula, O. | 5,800 | 51,968.00 | 51,968.00 | 49,358.00 | 46,632.00 | 45,675.00 | 44,834.00 |
| Buffalo, N. Y. | 1,670 | 12,909.10 | 12,909.10 | 11,973.90 | 11,973.00 | 11,973.90 | 13,660.60 |
| Cincinnati, O. | 113 | 1,241.84 | 1,241.84 | 1,241.84 | 1,190.94 | 1,164.93 | 557.58 |
| Grand Rapids, Mich. | 1,118 | 13,024.70 | 13,024.70 | 13,024.70 | 13,521.60 | 12,275.64 | 10,520.38 |
| [Other destinations and figures pertaining to them have been omitted.] | | | | | | | |
| Total costs | | 317,728 | 323,800 | 312,083 | 315,575 | 314,830 | 329,563 |

One may think that if it costs 30 cents to ship a commodity 100 miles it should cost something like $3 to ship it 1000 miles, but freight rates have been built up on a system of literally "charging what the traffic will bear." It has been to the interests of the railroads to help build up business for industries on their lines, and when one of these industries could show where they absolutely required a lower rate to develop new business or to invade a territory served by a competitor, the railroads have tried to help them. For example, industries located in New England on the New Haven Railroad have the same freight rates for points west of Harrisburg as those shipping from New York City.

Special import rates exist at a few ports and help to put these ports on a better basis in competition with other seaboard cities. For example, a domestic rate from Boston to Bloomsburg, Pa., is 34 cents, while the import rate is $25^1/_2$ cents.

### Commodity Rates

Special products have been favored with commodity rates from and to certain points where a special demand has existed. A manufacturer should always present his request for such a rate to his railroad if he can show that his competitor has a commodity rate and thus is securing an unfair advantage to reach a certain market. The possibility of securing additional commodity rates must always be considered in plant-location work.

### Cost of Importing Raw Material

In the case under consideration, the largest tonnage of raw material comes from Spain in full cargo steamers drawing 25 ft. of water. This required a study of Government maps of harbors. As the cost of unloading and shipping any distance by rail was very expensive, it indicated that the plant must be on deep water.

A review of port conditions for the principal ports was made and a sample of the study for Baltimore is included to indicate the points covered. Due to the distance which these steamers must travel, the question as to which one of the North Atlantic ports was selected for the plant appeared to make no difference in the cost of ocean freight.

It might be added that the question of anchoring ships and barging raw material to a plant having shallower water was considered, but the two spots under consideration, namely,

[1] Consulting Engineer. Mem. A.S.M.E.

Presented at the National Meeting, Rochester, N. Y., Oct. 26–27, 1927, of the Management Division of The American Society of Mechanical Engineers.

Narragansett Bay and the Delaware Bay, were thought to be unsuitable for such operations due to high winds and ice conditions in winter months.

The raw material from New Hampshire amounted to 1220 tons per year, and the freight costs to different locations were about as follows:

| | | | |
|---|---|---|---|
| Boston | $5734 | Philadelphia | $8510 |
| Providence | 5841 | Wilmington | 8747 |
| New London | 6417 | Baltimore | 9979 |
| New York | 8064 | Norfolk | 11346 |

## Port Surveys

It was necessary to make a survey of expenses and working conditions at various ports, and that which was made for Baltimore is given here as an example. These expenses are summarized in Table 2.

TABLE 2 ACCOUNT OF EXPENSE OF A STEAMER DISCHARGING AT BALTIMORE

| | |
|---|---|
| Entrance at Custom House | $ 5.00 |
| Clearance at Custom House | 5.00 |
| Custom-House fees | 5.00 |
| Quarantine fee (health officer) | 10.00 |
| Running lines (in and out) | 5.00 |
| Fumigation (about) | 90.00 |
| Coopers, if required, $8 per day | |
| Tally clerks, if required (estimated) | 350.00 |
| Wharfage, no wharfage account, steamer at usual railroad berths, agency fee | 100.00 |
| Use of preliminary bond | 10.00 |
| Postage and miscellaneous | 10.00 |
| Telegrams, telephone, etc. (actual cost)(estimated) | 15.00 |
| Pilotage inward, say, 23 ft. at $5.50 | 126.50 |
| Pilotage outward, say 13 ft. at $5.50 | 71.50 |
| Tugs, docking, about | 75.00 |
| undocking, about | 75.00 |
| (No shifts figured.) | |
| Stevedoring, discharging 5000 tons at $1.50 per 2240 lb. | 7500.00 |
| Tonnage tax, 3800 net register tons | 228.00 |

Note: Average rate of discharge, 650 tons per weather working day of 8 hours.

each direct call, but the tax paid within any period of twelve months is not to exceed 10 cents per ton.

If vessels are plying between both 2-cent and 6-cent ports, the total tax paid within any period of twelve months is not to exceed 40 cents per ton.

Entrance and clearance charges made by Government authorities amount to $2.50 to $10 for entrance and $2.50 for clearance.

Brokerage fees are $5 for entrance and $5 for clearance.

Custom-house bond charge is $10.

*Dockage and Wharfage.* Vessels discharging or loading at piers owned by railroad companies do not pay any wharfage if any portion of the cargo moves over the railroad where vessel is berthed. On material moving over side or over the dock of a railroad other than the railroad owning the pier at which steamer is docked, there will be a top wharfage charge of 12 cents per 2000 lb. This also applies on freight delivered to lighters of railroads other than the railroad at whose dock the steamer is discharging.

*Towage.* Towboat companies have fixed tariffs. The average cost of a shift is $80 to $100. The average cost of docking and undocking is about $60 to $70 total per steamer.

*Boatmen.* Charges for running ship's lines are $3 for mooring and $2 for unmooring each shift.

*Watchmen.* The rate for watchmen is about $4.50 per day of 12 hours.

*Stevedoring.* Rates of stevedores depend upon the commodity to be handled.

*Tally Clerks.* Clerking is contracted for by the ton or by the day.

*Water.* Fresh water can usually be obtained at the railroad piers at a cost of $1 per 1000 gallons. Delivery by boat is 65 cents per ton.

*Surveyors.* For inward cargo, the hatch-survey charge is

TABLE 3 ESTIMATED COSTS OF PLANTS—AN APPROXIMATE COMPARISON

| | If built at | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Boston | Providence | New London | New York | Philadelphia | Wilmington | Baltimore | Norfolk |
| Buildings and equipment | $ 840,000 | $810,000 | $810,000 | $890,000 | $840,000 | $785,000 | $790,000 | $780,000 |
| Land | 100,000 | 80,000 | lease | 100,000 | 85,000 | 50,000 | 70,000 | 40,000 |
| Dock or bulkhead | 70,000 | existing | existing | 60,000 | 55,000 | 50,000 | 40,000 | 40,000 |
| Dredging | 25,000 | none | none | none | none | 25,000 | 30,000 | 35,000 |
| Grading | 20,000 | none | 5,000 | 15,000 | 10,000 | 25,000 | 15,000 | 20,000 |
| Piling for plant | 75,000 | 30,000 | 40,000 | 75,000 | 15,000 | 35,000 | 25,000 | 20,000 |
| Approach railroad | 20,000 | existing | existing | existing | 15,000 | 20,000 | 10,000 | 12,000 |
| Approach road | 8,000 | existing | existing | 15,000 | existing | 10,000 | existing | 5,000 |
| Water supply | 10,000 | existing | existing | 40,000 | 15,000 | 15,000 | 10,000 | 25,000 |
| Total cost of plant | 1,168,000 | 920,000 | 855,000 | 1,195,000 | 1,035,000 | 1,015,000 | 990,000 | 962,000 |

*Pilotage.* Rates for pilotage for Chesapeake Bay: Vessels drawing more than 13 ft., $5.50 per foot deepest draft.

*Quarantine.* Federal quarantine station is located about six miles below Baltimore. Each vessel is charged $10.

*Fumigation.* Fumigation is performed by the U. S. Public Health Service only.

*Custom House.* Vessels coming directly from foreign ports, except ports situated in countries enumerated below, must pay a tax to the Federal Government of 6 cents per ton net register for each entry, but the total tax paid within any period of twelve months is not to exceed 30 cents per ton.

Vessels plying between the United States and the following countries are subject to a tonnage tax of 2 cents per ton net register for each direct call, but the tax paid within any period of twelve months is not to exceed 10 cents per ton: Canada, Bermudas, Mexico, Bahama Islands, West Indies, Central America, and that portion of South America bordering on Caribbean Sea up to the Orinoco River.

American, Norwegian, and Swedish vessels plying between ports of Norway, Sweden, and the United States are required to pay a tonnage tax of 2 cents per ton net register for

$15. For outward cargo, the New York Board of Underwriters' survey charge is usually $15.

*Bunker Oil and Coal.* Bunker oil and coal can be secured at favorable rates and upon short notice.

## The Cost of the Plant

A considerable variation was found in the cost of buildings and equipment erected in the different localities. The labor-union regulations such as prevail around New York boost costs materially in such cities. This was especially true in concrete and pipe work.

In the study of the properties available, the existing buildings, roads, and water supply were of course taken into consideration as well as the amount of piling required for buildings and docks and especially the length of piling that would probably be required.

Taxes also were determined as they entered into the cost of plant overhead. Dredging became an item in plant overhead when docks would not have extended to government channels.

## Real-Estate Surveys

A personal inspection was required of properties available, and

TABLE 4 SURVEY OF PROPERTIES AVAILABLE AT BOSTON

| Description of Property | Approximate cost of land |
|---|---|
| No. 1. On Mystic River. Requires dock and piling for plant and some dredging | $200,000 |
| No. 2. On Commercial St., served by deep water on the Charles River. Dock required but no dredging | $400,000 |
| No. 3. On Chelsea Creek. 25 ft. of water at property. Dock required | $100,000 |
| No. 4. Medford on the Malden River. A barging proposition up the Malden. This is marsh land. Requires dock, piling for plant, no dredging | $40,000 |
| No. 5. East First Street, South Boston, near Army Base. Assumed value | $400,000 |
| No. 6. On Malden River, near U. S. Government property. It would be a barging proposition | $20,000 |
| No. 7. South Boston, on Boston Harbor, 1/4 miles from 35-ft. channel. A channel 50 ft. from property to main channel would cost $75,000. Has railroad siding | $175,000 |

in one investigation all properties along the Atlantic Coast having 25 ft. depth of water and large enough for the plant from Maine to Virginia were investigated. The results are given in Table 3.

TABLE 5 A COMPARISON OF THE PRINCIPAL VARIABLES IN OPERATING COSTS FOR DIFFERENT LOCATIONS

| | Boston | Providence | New London | New York | Philadelphia | Wilmington | Baltimore | Norfolk |
|---|---|---|---|---|---|---|---|---|
| Delivery expenses on raw material from abroad | $77,630 | $80,505 | $80,460 | $32,225 | $81,125 | $79,080 | $76,080 | $79,980 |
| Freight on domestic raw material | 5,734 | 5,841 | 6,417 | 8,064 | 8,510 | 8,747 | 9,779 | 11,346 |
| Overhead on plant | 93,440 | 73,600 | 68,400 | 95,600 | 82,800 | 81,200 | 80,000 | 78,200 |
| Fuel | 73,815 | 73,815 | 69,375 | 64,935 | 61,605 | 61 605 | 58,905 | 55,944 |
| Factory labor | 250,000 | 225,000 | 225,000 | 275,000 | 225,000 | 200,000 | 200,000 | 175,000 |
| Freight on finished product | 317,728 | 321,621 | 323,800 | 312,082 | 312,960 | 315,575 | 314,830 | 329,563 |
| Land rent | .... | .... | 4,000 | .... | .... | .... | .... | .... |
| Totals | 818,347 | 790,382 | 777,452 | 838,906 | 772,000 | 744,307 | 739,994 | 730,033 |

For brevity only the survey of the land found available at Boston is included in this paper. The results are found in Table 4.

## Variation in Factory Wages

From information available, common factory labor rates appeared to run about as follows:

| | |
|---|---|
| Norfolk | 35 cents per hour |
| Baltimore | 40 cents per hour |
| Philadelphia | 45 cents per hour |
| Wilmington | 40 cents per hour |
| New York | 55 cents per hour |
| New London | 45 cents per hour |
| Providence | 45 cents per hour |
| Boston | 50 cents per hour |

The payroll on the basis of Boston was estimated at $250,000 per year, and as all general factory labor in the various localities varied about in proportion to the common labor, the payrolls for the various districts were about as follows:

| | |
|---|---|
| Boston | $250,000 per year |
| Providence | $225,000 per year |
| New London | $225,000 per year |
| New York | $275,000 per year |
| Philadelphia | $225,000 per year |
| Wilmington | $200,000 per year |
| Baltimore | $200,000 per year |
| Norfolk | $175,000 per year |

## Summary

From Table 5 it seemed evident that Wilmington, Baltimore, and Norfolk warranted further study. Points south of Norfolk were ruled out as freight costs would rise very rapidly with no counterbalancing advantages. In fact, with general offices in New York City, it was felt that Norfolk was too far away. On the other hand, Baltimore, which was not much more than four hours of travel by train from New York, had a better skilled-labor market, and a more intensive study of this section disclosed a site superior to any of those that had been reviewed in the previous comparison. After the final check was made, Baltimore was chosen as the best location.

# Manufacturing and Wage-Payment Methods as Practiced by the Hall-Scott Motor Car Company

By ALFRED B. CELANDER,[1] OAKLAND, CALIF.

IN DESCRIBING the Hall-Scott practice of manufacturing parts for their engines, we shall start with the blueprint at the time it is approved and released for production.

The planning department, after ascertaining the quantity and daily requirements of a part in question, will work up the following details:

1 Lay out a line of operations, giving the shortest production path possible which is consistent with good practice.

2 Give operation number, name of operation, locating points for progressive tooling-up, name of machine most adaptable, number of machine, estimated time to perform operation, estimated minimum number of pieces per day.

3 Designate what special tools will be required, such as drill jigs, locating fixtures, piloted boring bars, reamers, form tools, and gages. The standard tools required, such as milling cutters, arbors, drills, reamers, and taps and spot facers are also listed.

4 Make rough sketches of such tools as must be made to conform to layout and time element of that particular part. These rough sketches convey to the tool designer later on the original idea of the tools as figured in layout, saving on designing time and standardizing the design of tools, an item in itself worth considering.

If the production warrants it, a "line-up" or a "gang" of machines will be arranged, taking the utmost care to machine the part in question properly. The time limit is set for the machine, and tools are designed in keeping with the quantities to be produced.

In laying out a line-up, it is essential so to dissect the work to be performed that operations of a similar nature, such as all milling and drilling, may be done in proper sequence with a forward movement toward the finish end of the line.

When an operation is necessarily slow, as, for instance, in a reverse-gear or chain housing, where several gear centers, bearing diameters, and shoulders must be bored and faced in one fixture, the time required to make one piece generally sets the maximum output of that particular line-up. If this maximum output is sufficient, then the following and shorter operations are done by one or several men following the work from one machine to the other to even up the time of the longest operation, thereby eliminating lost time and giving uninterrupted and continuous production.

Where one machine will not produce the required amount, it is practical to place two or more similar machines abreast in the line-up, and arrange for parts to be spread out to be conveniently handled by these several machines. After passing through this operation, the parts are again brought together and finished in a single line.

In the Hall-Scott plant each machine has its individual electric motor attached to or integral with it. This makes it possible to place the machine exactly where it is needed or to move it to a new location on a moment's notice should occasion, such as a material saving of time, so require.

[1] Plant Engineer, Hall-Scott Motor Car Company.

Presented at a meeting, May 31, 1928, of the San Francisco Section of The American Society of Mechanical Engineers.

It may seem a trivial matter to move a production part a few feet or to the next aisle for the next operation, but as a matter of fact, this is wasted time and in many cases requires more time than is actually required to do the work.

We find the line-up method, if organized properly, to be, in many respects, the ideal way of manufacturing for the following reasons:

It stimulates the operator to do his best to keep up his part of the work.

It breaks the monotony of the work, as the workman in most cases performs several operations and is kept busy arranging his work.

It serves to eliminate spoilage, as the workman is doing the same thing over and over again and quickly detects any irregularity in the part.

It tends to improve workmanship, as each man is made to understand that he is responsible for everything passed by him.

It tends to act as a check on itself, as jigs and fixtures are used, wherever possible, which locate the part by the previous operation and thus prove and lessen inspection.

It saves inspection time, as line inspectors are provided with suitable inspection tools. The final inspection may, in many cases, be eliminated, and the part moved directly to the assembly line, or stock, as case may be, reducing chances for breakage and damage to parts in transit between operations and departments, in this case saving non-production labor and floor space.

The mechanical handling of parts is well organized at the Hall-Scott plant. The rough materials, after being inspected, are placed on platforms or in boxes and are distributed throughout the plant by electric lift trucks. In the line-ups the roller type of conveyor is standard if the part is too heavy to be easily lifted. For the lighter parts, as, for instance, the piston and connecting-rod line-ups, special chutes are provided to slide parts from one operation to the next. For still heavier parts and for parts that will not slide or roll, there are jib cranes and overhead monorails from which are suspended various lifting units, with air hoists predominating. Compressed-air hose for cleaning out jigs and fixtures are suspended on counterbalances within reach of the operator, but out of the way of oil and the part in production. Nut drivers and stud setters, both pneumatic and electric, are also counterbalanced. In heavy-duty work they are attached to sliding members to protect the operator from injury.

Inspection is very rapid, and limit gages of a heavy type set the go and no-go.

Cleanliness is essential on all parts and is effectively handled in splash or spray washing machines of the link-conveyor type.

Painting is done by means of a spray over down-draft exhaust grates. With this system it is not necessary for the painter to breathe through the customary wet sponge. In the old spray-booth system the painter had to work in the fumes or fog-like mist of the poisonous and explosive gases from the paint, which endangered himself and surroundings. In the down-draft system these fumes are drawn downward through grates and

out of the building, never having time to settle, and thus gas pockets and accumulations of paint around the spray booth are eliminated. These grates are easily removed for cleaning. The pits have sewer connections and are washed out regularly. The doing away with the sponge alone has saved a lot of time, as proper care had to be given to it regularly.

The laboratory makes a chemical analysis of all materials used, and it also gives a complete physical-property test to all heat-treated parts.

There are two dynamometer rooms at the plant, in one of which there is a 400-hp. a-c. dynamometer and in the other a 300-hp. Sprague electric dynamometer. Engines are given a final run, adjustment, and performance test to determine accurately that they are in all respects up to specifications.

### Incentive Wage-Payment System

In order to establish uniform costs for various parts, an incentive wage-payment system has been adopted which is cutting down production variations to a minimum.

The system used at the Hall-Scott plant is not built on the basis of speeding up machinery to a point which will shorten the cutting life of tools and possibly endanger the quality of the product. On the contrary, it was found, after a careful study of the situation, that the biggest factor to be dealt with was the time which was lost by the operator between the handling of successive pieces of work. In many cases this lost time exceeded the actual working time.

It was found that several factors might account for this lost time. One of these was the placing of materials so that they were unhandy for the operator to reach, causing undue fatigue and possibly creating a tendency toward carelessness. Another was that quite often the parts being worked upon would not fit the jigs or fixtures properly, making it hard to set and replace the work. These faults corrected, still another was found which was probably the most common, indirect cause of this lost time. This was lack of interest in the work to counteract the monotony of repetition. With this in mind a method was sought of adding an incentive for the workman which would benefit both himself and the company.

As a basis on which to work it was decided to find the net time required by a good man to perform any operation, at a speed guaranteeing good quality with the best tools available, and done on a machine assigned to do the work. For performance in this time the company would allow an incentive pay of $1^1/_4$ times that for the time consumed. To this net time was given the name of "best time" per piece, which, if kept up throughout the day would give a maximum production under the most favorable conditions. But as a maximum standard would tend to hold down production, it was considered best not to use this expression, so that it is employed only for calculations in arriving at the results of problems.

It was found more desirable to establish a minimum number of pieces that an ordinary operator should turn out in a standard 8-hour day. This minimum number of pieces was set at 75 per cent of the maximum. For this the operator was allowed his day rate. The time it takes to make one minimum piece is called "standard time." Standard time gives the standard cost of operation. For every piece made above minimum, a bonus of 75 per cent of the standard cost is allowed as an incentive.

As each individual operation must be analyzed and treated by itself, there has been developed a sheet called the "time-study record." On this form, the time-study man records all characteristics, incidentals, and a step-by-step analysis of speeds, feeds, cuts, and special tools, if any, used in arriving at the observed time on the several pieces. From this the best time is determined. By adding 33.3 per cent for tooling and contingencies the standard time is obtained. Standard time multiplied by hourly rate would give standard cost; but as day rates vary, two standard day rates have been established, one of $4.80 to apply on all operators under $6 per day, and $6 for operators receiving $6 or more. This makes the full bonus respectively $1.20 and $1.50, or 25 per cent of the two standard day rates. This gives the operator rated at $4.80, $6 per day, and the $6 operator, $7.50, when the full number of bonus pieces is made, which is always possible if all time between pieces is accounted for and utilized and if no undue tool trouble occurs.

A route card is issued in duplicate by the production department, giving the number of the department to do the work, the operation, the set-up time, the minimum number of pieces, and the bonus rate. The original is given to the department foreman and the manila-card duplicate is slipped into a celluloid container and follows the material until the job is finished.

In starting a new job lot the set-up time must be taken into account. This is also given on the time-study record and is the longest time it should take to get a machine or job under way. If the foreman finds that the job requires less time for set up than is stated on his production order, he will write in what time he allows on the next job card which is issued to the man who is to do this particular operation. The operator turns in the next job card to the timekeeper and receives his operator's job card with clocked time of starting the job and other information needed, such as set-up time, minimum pieces, and bonus rate.

This system applies as well to groups as it does to individuals. Take for instance the case of the connecting rod and its cap. Both of these have been produced on the bonus plan for three months or more. The rod goes through 22 machining operations in a line of machine tools with a group of seven men. Each man attends to from 3 to 4 operations, thus dividing up the work equally. The best time is 0.03333 hr. and the standard time is 0.04444 hr. The hourly rate for this class of workman is $0.60, making the standard labor cost per operation $0.02667. Hence the minimum for 180 pieces is $4.80. Taking the last three days' output of this particular part as 234, 236, and 238, or an average of 236, and subtracting the minimum of 180, there are left 56 pieces for which the men are entitled to a bonus. Seventy-five per cent of the standard cost of $0.02667 is $0.02, which is the bonus on 56 pieces, or $1.12 bonus money to be added to each man's day rate. The total earnings of these seven men on May 8 were as follows:

| | | | |
|---|---|---|---|
| Clock No. 20, day rate | $4.80 plus bonus | $1.12 = | $5.92 |
| Clock No. 21, day rate | 4.40 plus bonus | 1.12 = | 5.52 |
| Clock No. 34, day rate | 5.44 plus bonus | 1.12 = | 6.56 |
| Clock No. 77, day rate | 6.00 plus bonus | 1.12 = | 7.12 |
| Clock No. 93, day rate | 5.54 plus bonus | 1.12 = | 6.66 |
| Clock No. 94, day rate | 4.00 plus bonus | 1.12 = | 5.12 |
| Clock No. 212, day rate | 3.64 plus bonus | 1.12 = | 4.76 |
| Total for machining 236 rods............ | | | $41.66 |

In dividing cost by rods made the result is $0.1765 for the seven men's work per rod ready for assembly. The last previous day-work record showed a cost of $0.5134 per rod, which is 190 per cent higher than the present cost.

The cap for the connecting rod in question is made in a separate line-up. There are nine operations and three operators. The best time is 0.03167 hr. The standard time is 0.04222 hr. The standard cost is $0.02534 × 3 operators, which amounts to $0.07602 per cap ready for assembly. The last previous day-work cost was $0.2623, or 245 per cent higher than the present cost.

There is another advantage of this line-up and bonus pay that might be worth pointing out. Let us suppose that we start this line with seven men. At first every one is busy keeping his allotted machines going, but after everything is running smoothly each man finds time to do a little more, so that eventually the crew can be reduced to six men. This does not alter the time-study record materially, but just rearranges the operators and pays six instead of seven men, saving one-seventh of the cost.

When the bonus payment system is completely installed, it will be possible to tell, not alone the labor cost of the parts, but also the exact amount of individual machine time necessary for a given number of motors per day. This, in turn, will govern the number of men required in the production departments, and it will also show whether it will be necessary to work overtime on any machines in order to meet production requirements.

To facilitate the work of the time-study man, a set of tables has been worked out. One gives the seconds and minutes consecutively from 1 to 60, converted into decimals of one hour. Another gives the bonus rate to minimum pieces from 1 to 200. In order to distinguish the lower bonus rate from the higher, the latter is prefixed with a zero, making it permanent and always to be written that way. For instance, the bonus rate of 019 = $0.23684 gives the higher rate as against the bonus rate of 19 = $0.18947 for the lower.

The contention that spoilage is kept to a minimum with the line-up and bonus payment system was upheld on a check of 1143 connecting rods that were finished on May 10. The first operator lost three by misplacing them in one of the milling fixtures, the third man misplaced two in a drill jig and one in straddle-milling operation, a total of six spoiled and 1137 passing. It will be noticed that five men out of this seven-man line never missed once, and in all but one instance caught the spoiled rod on the next operation. This is about half of one per cent spoilage, which must be considered good.

## Discussion

Arthur B. Domonoske.[2] The paper comments on the speeding-up effect of the work on the conveyor coming to the operator, but the writer believes that the work leaving the man has as favorable psychological effect on him as the pieces coming to him. Any observing stockchaser soon learns to remove rush jobs from the vicinity of the workman as soon as they are completed, even if the need of haste no longer exists. In the line, the workman actually sees the work on the way to the next station and also notes how urgently it is needed. This may result in spurts of speed at the time most vital to keep the line going when otherwise delay might arise from lack of parts.

Several questions occurred to the writer in reading the section on the bonus system, as:

There are two standard day rates, $4.80 and $6.00, with a possible bonus on the connecting-rod job of $0.02 and $0.025 per piece respectively. In the table shown, the $6 man receives the same bonus as the $4.80. In general, would the $6 man in the $4.80 line receive the higher bonus or the bonus common to the group?

When the shop is completely changed to the bonus system, will the foremen of the departments receive additional compensation? The writer has noticed much discontent among set-up men on automatics, where the operators were able to earn good money on piece rates while the men responsible for the set-up were paid day rates.

[2] Executive Head, Mechanical Engineering Department, Stanford University, Calif. Assoc-Mem. A.S.M.E.

Although not mentioned in the paper, what provision is made for machine repair? Does the company rebuild or have some other firm rebuild machine tools? In other words, is it economical to rebuild an old machine or would scrapping be better?

S. S. Jacobs.[3] Before proceeding with the discussion or any details concerning this particular production system, it might not be amiss to check up to see what a production system should consist of basically.

### Basic Production Units

The following broad divisions into which production work might be grouped will take care of all major requirements:

1 A proper detail blueprint to contain all necessary information and dimensions, properly toleranced material and its treatment, tooling record, and change record

2 A planning department to decide operations and their sequence, and also time study and rate setting where used

3 A production department to see that necessary materials are ordered and that the planned program is carried out by a follow-up system

4 A properly balanced manufacturing organization

5 An efficient inspection system to maintain the necessary quality and accuracy standards of the degree of interchangeability and accuracy necessary

6 A cost-finding and audit division.

The Hall-Scott system as outlined in the paper presented seems to cover the production requisites as outlined and shows a well-balanced organization. Production systems have proved their merits in cost cutting, increasing output, while still maintaining quality and interchangeability. They must, however, be custom-made to suit each individual business. The system which functions perfectly in one plant might be very inefficient in another. There are several interesting production applications in the description of the Hall-Scott system. One of them is the application of straight-line production, and the other, the application of the bonus system.

### Straight-Line Production

In discussing straight-line production, it is of course obvious that a fairly large quantity of parts, and reasonably continuous manufacture, would have to be present in order to use the method advantageously. As an example: A connecting rod of which 1143 parts were manufactured, cost 26 cents each, or a total of approximately $297. This line would need a fairly permanent set-up and continuous operation or there would be a considerable increase in cost. The set-up and tear-down cost of tools for this $297 worth of work would be rather high for this output if interrupted before complete. Very often, on the other hand, if there were not sufficient work for continuous operation, the cost of machinery standing idle in the straight-line method would not be economical, if not used for other parts.

### Service to Customer

The problem of service and parts supplied to customers also enters into this plan. It is not always possible or economical to carry too large a stock of service parts. If the stock gets below the level, any manufacturing of service parts will probably interfere with a straight-line system of producing parts for a regular run of machines. If an emergency order for parts which had to be rushed were received, it would upset the predetermined planning program on a straight production line where the machines are grouped in the proper sequence for the manufacturing or assembly

[3] Chief Draftsman, American Can Company, San Francisco, Calif. Mem. A.S.M.E.

of units. These extra parts are sometimes taken care of by overtime or extra shifts. Neither method is always economical where parts are sold by pre-set catalog price and figured on regular production-cost basis.

### Flexibility in Forming Machine Line-up

While flexibility in tool placement and arrangement seems an ideal scheme, the majority of production tools today are very heavy. They require good foundations which are permanent, to meet modern production demands. It is rather difficult to have most production machinery, even though motor-driven, taken from place to place and arranged with very little time elapsing before machine is ready for production.

While considerable time is undoubtedly lost in transferring work from machine to machine and from operation to operation, this can be reduced to a rather small figure by modern means of transportation. In a concern where a great many parts and a good many different machines are manufactured in rather small quantities, it is a difficult matter to group machines unless the amount of equipment is increased. In place of this investment in extra equipment, the money could be invested in quick transportation units, either mobile in character, such as hand or electric trucks, or stationary permanent units, such as roller conveyors, elevators, and the like.

The author mentioned the use of as many of these modern methods of part transportation, along with the straight-line units, as seemed feasible. It seems improbable, however, that beyond such machines as light lathes, drills, etc., most of the major heavy machines in modern manufacturing could, as now designed, be moved around at a moment's notice. If such machines, mobile in character, were made, they would be of the lighter variety or perhaps of special design for special-purpose work.

Opposed to this idea of straight-line manufacture, the same class of machines might be distributed in unit lines, in various parts of the plant in a machine-group plan. This consists of placing each group of similar tools as a unit with a trained foreman in charge of each group. One foreman is in charge of mills, another one, of drills, another, planers, etc., and this makes for considerable efficiency in both foreman and operators in each department. The benefits of this group system are entirely lost in a straight-line set-up.

### Straight-Time and Bonus-System Work

The second major item of interest in the paper presented is the development of a special bonus system. Again, the matter of quantity production comes to the fore. Where parts are not made in quantity, the economy of bonus or premium system is questionable. This has been proved in the concern with which the writer is connected and in which four of the Eastern manufacturing plants operate under the premium system as against the San Francisco plant which operates on day labor. In San Francisco with a greater variation in the number of parts manufactured per employee, the production quantity per part does not warrant the overhead expense involved. The larger quantities manufactured at the Eastern plants allow sufficient leeway for extra cost of clerical work necessary for bonus or premium pay. The premium method seems to be a better system, however, than either day work or straight-line work as used by Hall Scott Co., and offers a solution of rate setting for both the fast and slow man.

For the shop where premium-system overhead is too great, may be mentioned the matter of foremanship. The alert high-class foreman goes a long way to offset, in a straight-day-work-payment shop, the gain which is made in other plants by using the premium system, it being understood, however, that a production system is followed in both cases and work is planned.

As an example: In the San Francisco plant of the American Can Co., which is without a premium system, but where work is planned, and where the tooling is equal to that of the Eastern shops using the premium system, the costs have been practically the same when from ten to one hundred pieces were produced at one setting. When the number of parts increased from 250 to 1000 at one setting, the effect of the premium system is noted. The quantity of parts allows a man a chance to get the swing of work and the handling of tools, and parts are produced faster as the work progresses, so that naturally the cost is reduced with practically no rise in spoilage percentage. The key to this whole subject is undoubtedly sufficient quantity. Just where the line may be drawn as to what quantity, and with what tooling, premium work would have its best effect, is a rather hard thing to determine. It must be worked out for each individual concern according to its needs.

The paper states that the bonus system has been installed with practically no extra clerical work involved. It would seem rather a difficult matter to install time study, rate setting for bonuses, and continuous adjustment of these from time to time without additional clerks, study men, and the systematic gathering, recording, and revising of data for a shop producing large quantities. This additional overhead, if it develops, is soon absorbed in the profitable results obtained. A shop producing small quantities of each part would probably find this system too detailed for profit showing.

The standard of foremanship is becoming more and more an important function in manufacturing procedure. This is particularly true where a variety of production parts must be manufactured in relatively small numbers. The foreman thus becomes the key figure in an operating or production system, rather than the individual urge of each mechanic due to any bonus or premium system. While a straight-line set-up, as described in this article, is an excellent one where it can be applied, the application can only be ideal in a relatively small number of plants. The average number of men, according to statistics, employed in manufacturing plants, is under a hundred men per plant in the U. S. As there are many large Eastern units employing thousands of men in one plant, it can readily be seen that there must be hundreds of small plants to a few large ones. The total production of the small plants amounts to an enormous figure, and with the ordinary man purchasing these productions and paying, in the cost, all the inefficiencies which exist in small plants, it seems that the necessity for a production system adaptable to small organizations is just as necessary as such methods as are described in this article which are applicable to only fairly large units.

At this point it might be stated that there are a great many large manufacturing plants which do not find it economical, because of the size of production machinery and other features, to use straight-line methods.

The writer's personal observations of a considerable number of Eastern plants, such as machine-tool builders, were that only a few of the units are given what might be called straight-line manufacturing progress to a given assembly point. The method of manufacturing eight or ten parts in gang machining is used in preference to manufacturing single parts in a straight process. Under this system of group machinery rather than straight-line process, the piecework system is used perhaps more than the premium. Each operator working on an individual machine is responsible only for what he produces, and the speed of an operator behind or in front of him has no effect on the amount of work which the individual can produce.

### Corrections and Rejections

No mention was noticed in the article as to methods of handling

corrected and rejected parts. The higher the degree of interchangeability and quantity demanded, the greater the percentage of corrections and rejections. This will be so whether inspection is automatic by checking jigs or personal by inspection gaging. This would also be so whether inspection is for each operation or only the finished work.

Corrections and rejections may be brought down to a minimum, but they can never be entirely eliminated. They must be considered in any bonus system. The division of the losses in such parts between employee and employer is usually a sensitive matter. While the method of adjusting in the Hall-Scott system is unknown to the writer, he feels that the giving of a bonus of 75 per cent of time only for work over standard time is very liberal, and he wonders if the spoilage and correction adjustments are taken out of this time of employee or are absorbed by the company.

Another matter of vital importance in such systems is the effect on men not directly making parts but indirectly responsible for speed of work produced by premium-receiving employees. If the foreman is not allowed a premium in proportion to the men in his charge, the best results cannot be expected. If the men supplying material, treating material, etc. are not considered in such a system, there will be possible lapses of efficiency in system.

At this time the writer would like to outline a system which includes consideration of all persons concerned in producing parts at a rate above standard, and who ought to receive some consideration from results obtained over standard. This system consists of, first, a standard cost set on each operation, the rate to be set in hours or tenths of hours rather than in dollars and cents. Thus, the time cards and payroll for any employee, irrespective of his day rate, can be easily balanced. Second, penalty time is deducted from the time saved according to the pieces corrected and rejected in lot manufacture. The premium is figured by taking actual lapsed time for a job, divided by the total number of pieces, and to this lapsed time is added penalty time for corrected and rejected pieces. This, subtracted from standard time, gives the premium time allowed. An example of this would be as follows:

Suppose that out of 100 pieces made, 87 were good, 10 were corrected, and 3 were rejected, and the total time worked on original pieces was 75 hr. This represents 0.75 hr. each. The penalty time would be 13 pieces multiplied by 0.75 hr. which equals 9.8 hr. actual time. Seventy-five hours plus 9.8 hr. penalty time gives 84.8 hr. gross elapsed time. If the standard time were one hour each, the 87 pieces would take 87 hr. The allowance for corrected pieces plus the 87 good is 84.8; a total saving of 2.2 hr. for which premium would be allowed on the job.

The premium is divided so that 50 per cent goes to the employee directly making parts and 50 per cent to the company. The company in turn takes 20 per cent of its portion and places it in a so-called premium fund. This fund is divided among those persons in the plant who are in a position to increase production through direction or supervision, called class "A" employees. On the other hand, other indirect employees, such as those furnishing material, tools, power, or facilitating the progress of the work, would be classed as "B" group. In a system of this kind, it is obvious that executives, engineers, production men, inspectors, premium clerks, etc. could not participate in premiums.

The premium fund is divided as follows: 80 per cent of fund is given to class "A" group and 20 per cent to class "B." The total fund allowed to each group is divided by the number of men in each group participating, each receiving an equal share. Class "A" group consists of foremen, assistants directly supervising producing employees who receive 80 per cent of bonus fund. The "B" group consists of indirect foremen, such as pattern-shop, heat-treating, and tool-room foremen, etc., and such men as casting clerk, chief stock keeper, electrician, millwright, etc.

It can be readily seen that in such a system everybody concerned from the man handling the raw material to the man working on it participates in the premium and that a unified spirit of speed and production is produced. As an example of the average premium rates which can be earned, the following figures may be of interest. The premiums in four plants located in various parts of the United States vary from 4 cents an hour to 11 cents an hour in addition to standard wage, or from 5 per cent to 17 per cent. The department foreman in one month might average around $50 in additional wages on a premium basis, while the class "B" group participants average from $7 to $24 a month extra. These amounts are well worth while when one considers that the average standard rate paid is reasonably close to the day rate paid by some other plants.

### Author's Closure

Our bonus system, as started a year ago, is gradually working its way through all machine departments. So far we have found no serious obstacle in applying it. We have operations on parts that will take a whole day to perform and other parts of which 3584 pieces are finished in one day, with bonus applied just as efficiently with lots ranging from 25 pieces to a continuous run.

It is true that any system, in order to function, must be more or less "custom-made" in order to fit into the various lines of business; but the principle remaining is the same, therefore it can be readily applied.

As to our bonus rate: If a $6 a day man is temporarily in a lower bonus line-up, as it happened in the connecting-rod line at the time in question, he is paid the low bonus rate, but if it is a permanent job for a high-priced man, he gets the high bonus. Our additional clerical help on bonus costs less than 3 per cent.

As to rearranging line-ups, we do not hesitate in switching machines about, be they heavy or light, if production benefits by it. The only machines placed permanently are large Ingersoll milling machines and the largest sizes of boring mills. These machines are generally placed and the line-ups are laid out accordingly. The floors are heavy enough to carry all others without a special foundation.

As to toolsetters and foremen participating in bonus, the point may be well taken, especially in factories where their earnings are less than those of the man on bonus, but, may I say this. We have had the heartiest cooperation of everyone, men and foremen alike. The chief aim of all has been to bring the output up to meet time allowed without sacrificing quality.

Seventy-five per cent of standard cost paid in bonus on all pieces above minimum leaves 25 per cent which may be accumulated and used to advantage, in paying the cost of the system, a participating bonus, or new tools, as the management may decide.

Hall-Scott maintains a machine-repair and rebuilding department. If a machine is not suitable for one job a place for it can always be found on a single-purpose job where it will do as good work as a new high-priced machine would do.

# Motion-Study Principles and Their Application in a Department Store

By B. EUGENIA LIES[1] AND MARIE P. SEALY,[2] NEW YORK, N. Y.

*The fundamental principles of motion study are first presented, and are subsequently illustrated in the report of a study which was made of a centralized cashiering system in the department store of R. H. Macy & Co., Inc., New York.*

*After defining motion study and stating its benefits to worker, employer, and community, the authors describe the methods used by the motion-study analyst in attacking the problem of finding the best method of doing a particular job. The complete data relating to the job, the worker, and the environment are first collected. The sequence of operations involved in the job and related to it are recorded in a process chart, and in some cases a micromotion study is made, the actions of the worker being recorded on a motion-picture film. Placed in the scene is a special clock which shows the time to $^1/_{1000}$ of a minute, and thus makes it possible not only to study the motions, but to time them accurately. From these films, a simultaneous motion cycle chart is prepared. The data and records thus obtained in the preliminary study of the present method are used as a basis for making changes which will increase productivity, reduce fatigue, and save time. From these studies, the best method of doing the job is evolved. Tasks and rates can now be set and incentives established.*

*The case illustrating the principles described is presented in the second part of the paper. The factors affecting the work of the cashier are summarized and the results of the motion study discussed. Examples of the process and simultaneous motion cycle charts are given. The changes which were made in the working equipment, the work room, and the work of the cashiers are described, and the benefits which have resulted from the careful analysis are explained.*

Motion study is a method of analyzing work in order to eliminate needless, ill-directed, and ineffective effort, and the resulting unnecessary fatigue, and to utilize the necessary effort in the most economical way. It benefits the worker by placing the best-adapted worker on the job, by eliminating fatigue, and by increasing earnings; it benefits the employer by increasing production and decreasing unit costs; and it benefits the community by providing lower-priced commodities, greater purchasing power, and better-adapted and better-satisfied members of society.

## Method and Technique of Motion Study

"Motion study consists of dividing work into the most fundamental elements possible; studying these elements separately and in relation to one another; and from these studied elements, when timed, building methods of least waste." (Gilbreth, "Applied Motion Study," p. 48.) "The variables which must be studied in analyzing any motion group themselves naturally into the following divisions: (1) variables of the worker; (2) variables of the surroundings, equipment, and tools; (3) variables of the motion." (Gilbreth, "Motion Study," pp. 6 and 7.) "The accurate measurements involved in getting the best results include three elements. We must determine first the units to be measured; second, the methods to be used; and, third, the devices to be used." (Gilbreth, "Applied Motion Study," p. 44.) These devices should be as refined as necessary to get the best results, considering also how much time and money may be justified by the expected results.

The method employed by motion study includes, first, recording present conditions and practice. Under "conditions," the survey includes the surroundings of the worker, such as the lighting, ventilation, dust, temperature, humidity, odors, noise, etc. The work place and its relation to the worker are also studied, that is, the equipment used, such as desk or bench, chairs, etc., and also the tools and devices used. The work done is recorded in detail. For this purpose the process chart is used, and, in some cases, micromotion study. Both of these devices and their uses are discussed later in detail.

All other data relating to the job such as flow of work, peaks in business, records of past production, cost records, etc., are also gathered, as well as data concerning the worker, including the physical, psychological, and psychiatric factors influencing his work on the job. Information on age, sex, schooling, physical conditions, personality traits, and ratings on intelligence and psychological tests are included in the worker's record.

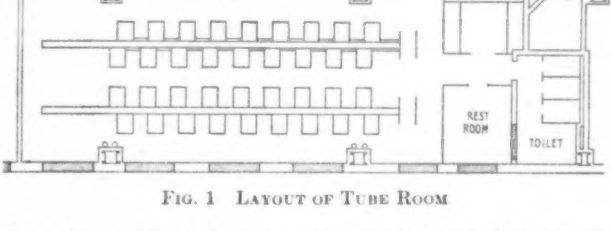

Fig. 1 Layout of Tube Room

## Other Steps of Method

After present conditions and practice have been recorded, the next step is to analyze the data, considering such points as the following:

(1) Is the work necessary? Does it contain any unnecessary elements, operations, or "therbligs?"[3]
- *a* Can these be eliminated entirely because they are useless?
- *b* Can they be eliminated by combination, substitution, etc.?

(2) *a* Can the necessary work be done with less expenditure of effort?
- *b* Is the arrangement of work, materials, and tools within the normal grasp area?[4]
- *c* Is the routing and scheduling most direct, providing continuous work, etc.?

[1] Director of Planning, R. H. Macy & Co., Inc.

[2] Assistant Director of Planning, R. H. Macy & Co., Inc.

Contributed by the Management Division and presented at a meeting, New York, N. Y., January 30, 1928, of the Metropolitan Section of The American Society of Mechanical Engineers.

[3] Gilbreth divided all operations into 17 elements of a cycle of motions which he called "therbligs." See "Management's Handbook," p. 809.

[4] Work done by Piacitelli and Allen (*Manufacturing Industries*, July, 1927) and Moeda and Lossagk in Germany has developed data on the normal grasp area and the best working area.

*d* Can improvements which will reduce fatigue be made in the surroundings of the worker?

Through the analysis of the data, possibility methods are developed, and finally the ideal solution is determined, including the best methods, the best conditions, and the best type of worker. However, the ideal solution may not be the one actually installed, since limiting factors, such as the cost of new equipment compared with possible savings, may force deviations from the ideal. The solution decided upon, however, must be the best practical solution, considering all of the factors in the situation. Developing the ideal solution is, however, desirable and essential even though it may not be installed in toto.

After the conditions and methods are standardized, the task can be set and an incentive plan decided upon. Then the problem of maintenance of the standard methods always arises, and for this purpose standing orders and instruction cards are used.

### Devices Used Depend Upon Problem

When the motion-study analyst is beginning an investigation, he decides how much and what elements of his technique he must use on the particular job. The character of the job decides this question. At times only a process chart will be necessary. On other more complicated jobs a micromotion study involving the use of motion pictures may be needed.

### Process Charts

Process charts are used to record in a simple compact form and to visualize the elements of a process in sequence and in relation to the entire process. They record present practice for the purpose of studying and analyzing the present practice, and also serve in visualizing possibility processes which improve the present practice by (1) changing the sequence of elements, (2) eliminating elements, (3) combining elements, and (4) substituting or changing elements.

As a record of standard practice, the process chart serves as an authoritative and complete picture of the entire process. It is particularly useful as a teaching device and as a means of maintenance.

At the top of a process chart there is usually a plan of the work place, with the arrangement of equipment and tools. The chart itself is made up of a series of symbols, connected by lines, indicating the sequence of operations and also the relationship of those operations, such as alternatives of process, separation of units, and combination of units. Such a chart, prepared in connection with the case illustrated in this paper, will be found in condensed form in Fig. 2. The symbols indicate:

(1) What—that is, materials and supplies, operation inspection, movement, storage of materials and supplies
(2) How—that is, word description next to symbol
(3) Who—name of job or mnemonic job symbol
(4) Where—work places, work rooms, etc.
(5) When—that is, sequence or if a definite time, in description next to symbol.

The "why" element is obtained by the analyst in his study of the chart.

### Micromotion Study

The other particular device used by the motion-study analyst is the micromotion study. By this method, a motion picture is taken of the worker at his work place with a clock included in the picture. A record is thus made of the method used, the time taken, and all the surrounding conditions (except sound).

Fig. 2 Portion of Process Chart Including Some of the Operations Performed by the Cashier

The data on the film may be studied at any convenient time and shown graphically on a simultaneous motion cycle chart, known as a "simo" chart, a sample of which is illustrated in Fig. 3. Such a chart indicates horizontally the parts of the body used and vertically the time consumed by each element of motion or therblig. The time is shown in units of $^1/_{1000}$ of a minute, which is possible because the clock included in the picture registers time in this small unit. As the data are taken from the film, the motions are split up into therbligs. Each of the 17 therbligs is shown in an individual color, so that it is possible to see from the chart the exact therbligs used and the time consumed by each.

By comparing the therblig analyses of all the methods used, the analyst can easily compare the differences in the various methods and can evaluate each. He is then able to complete his analysis and synthesize the best arrangement of therbligs into the best method.

### Value of Motion Study

Analyzing work by means of the principles and technique described above has the following advantages:

1 In the first place, this method considers every element influencing the work and thus effects improvements in every factor, that is, the surroundings, the equipment and tools, the method, the worker, and thus the time.

2 Motions are recorded as well as time, and thus the data on time are of real value.

3 In addition, this is the only method by which it is possible to analyze adequately operations involving short cycles or very rapid movements, since the elements of this type of work cannot be studied as accurately by the stop-watch method. Analyzing this type of work is very important, as often enormous savings can be made both in unit cost and in fatigue by analyzing these short-cycle or rapid-movement operations.

4 These devices are also valuable in studying a group of workers. It is, indeed, the best method to record what each worker is doing simultaneously when a group works jointly on an operation.

5 This method also has a decided advantage in recording the standard method as well as standard time. This is particularly valuable in setting a task.

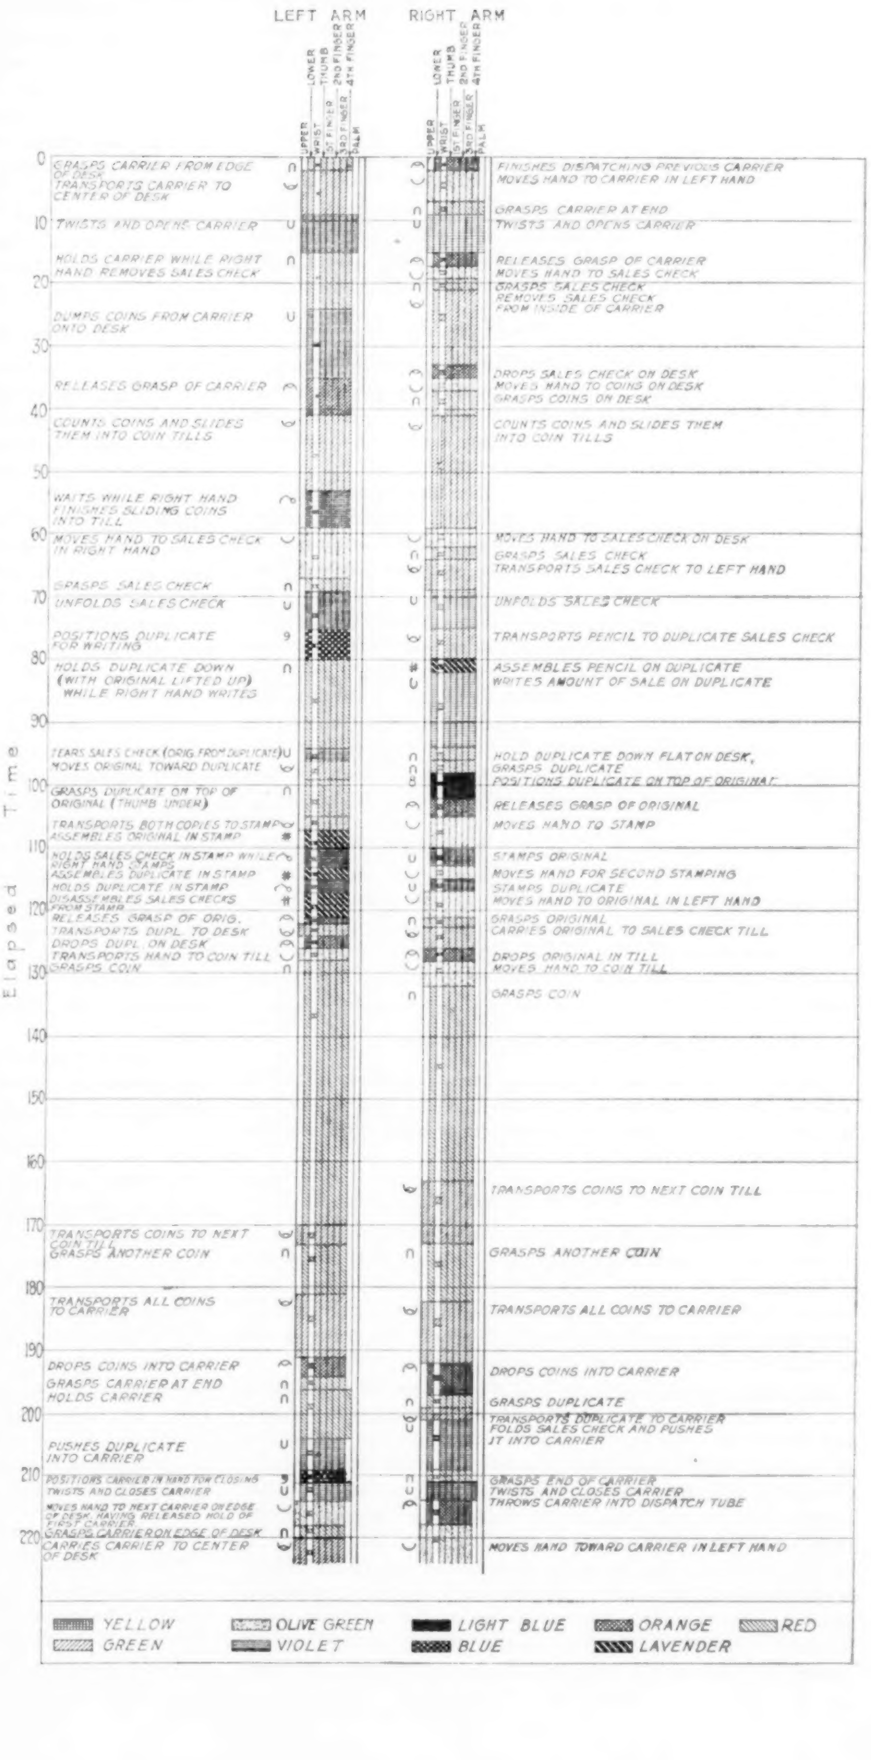

Fig. 3 Simultaneous Motion Cycle Chart

6 As a means of training the analyst himself, this method forces attention on all phases of a problem, develops a logical analysis of the job, and also develops keen observation in the elements of motion.

7 This method also permits recording times of fundamental motions or therbligs. This is important in building up standard times, when the elemental times are considered in relation to the variables.

8 As a means of training the worker, the micromotion produces acquisition of skill in a minimum time; first, by training in motions and thus developing habits of correct motions from the start; and, second, by providing a visual record of what is to be done.

### Application of Motion Study in Retail Field

Turning to a definite field, we find that the principles of motion study can be applied in the retail or distributing field as well as in the factory. This has, indeed, been done by R. H. Macy & Co., Inc., a retail department store in New York City, in order to perfect methods and systems, and to set tasks.

The technique, moreover, has been used on a large variety of jobs. It was used, for example, in analyzing conditions existing in the fur-storage department which receives coats from customers in the spring, stores them in cold vaults, and then delivers them to customers when wanted, usually in the fall. The entire work of the department is concentrated in a few weeks in the fall and spring. The fur-storage problem was largely one of determining the simplest, most direct, and most economical routing for the handling of the furs and the records involved; scheduling the work to take care of a tremendous peak, which lasts only a few weeks; providing the best methods for each job so that high production can be made on each job and, in addition, so that definite training can be given and the duties of each job learned in a minimum time.

The method has also been used in the furniture warehouse, in arranging stock in some of the selling departments, and in standardizing methods and setting tasks in correspondence, typing, and depositors' accounts (banking) departments. To illustrate the principles of motion study, the details of the method as applied to the analysis of the problems existing in the central cashiering department will be presented.

### Purpose of Cashiering Study

The study of the cashiering department was undertaken in order to improve the service to customers and also to decrease the operating costs of the tube rooms by increasing the production of the workers.

### Description of Department and Work

The tube rooms are the units of a centralized cashiering system to which the money received from the customer and two copies of the sales check are sent in carriers via pneumatic tubes. The carriers fall on a belt conveyor and are carried to the cashiers who sit at desks on either side of the belts. Fig. 1 shows the arrangement of one of these tube rooms.

The cashier grasps the carrier from the belt, opens it, withdraws the money and sales check from the carrier, counts the money and checks the arithmetic of the sales check, stamps both copies of the sales check, retains one copy, but places the other with the change in the carrier. She then dispatches the carrier by placing it into a tube from which it falls on to a lower belt conveyor which carries it to the switcher at the end of the belt.

The switcher sends the carrier back to the department where it is given to the sales clerk. In the meantime, the merchandise checker, located in the department where the sale was made, has been wrapping the package, so that both the package and the change are now ready for the sales clerk to give to the customer.

### Conditions Before the Study

Before the study was made, a bonus plan had been in operation in the tube rooms for several years. With this incentive, an increase in production had been obtained. Indeed, some of the cashiers had become very skilled in methods which each one had developed for herself, and had developed a high average production. The average production of most of the cashiers was quite low, however, and the time required for a new cashier to become skilled was from 3 to 4 months. This was a decided handicap at the time of the Christmas peak, because there was a possibility of giving very poor service to customers unless new cashiers were hired long before the peak actually arrived.

### Recording Present Conditions and Practice

The first step in the study was to record present conditions and practice. A survey of the surrounding conditions included the lighting, ventilation, noise, and vibrations.

Desk lamps on each cashier's desk illuminated part of the working area of the desk as much as 50 foot-candles (directly under the lamp), with variations down to 20 and 10 foot-candles on different parts of the desk. The general illumination of the room, however, ranged around 4 foot-candles, with parts of the room, especially the end and the corners, in deep shadows. The contrast between the brilliantly lighted spots on the desks and the meagerly lighted surroundings made the cashier adjust her eyes to the difference every time she raised or lowered them. This situation contributed to the fatigue of the cashiers.

The ventilation was good in all of the tube rooms except the one nearest the street. Here the dust from the street was so bad that it was out of the question to keep the windows open.

Nothing had been done to eliminate the noise caused by the vibrations of the air drums of the tubes and the whirring of the motors moving the belts. The noise was deafening, so much so that the ringing of the telephone, which was almost continuous, was scarcely heard.

The vibration of the floor of one of the tube rooms presented a very annoying problem. This tube room is over the engine room, in which the steam pipes were hanging from the ceiling directly under the floor of the tube room. The result was a constant quivering of the floor to which it was difficult to become accustomed.

The general layout and routing of work in the tube rooms had been previously studied, and after restudying the situation, it was decided that the present layout was the most desirable one.

### Work-Place Equipment

The work place and the equipment, however, were also studied in detail. The layout of the desk was studied in connection with the motions involved in the transaction, as will be discussed later. The old desks were 38 in. high, a little too high for comfortable working when the cashier was standing, but the desks were made that height to accommodate the height of the top belt. High chairs were used also, but these were of the swivel type on which the seat and back rest tilted backward and on which a circular hoop about 10 in. from the floor served as a foot rest. The chair was so awkward that the cashiers sat only on the front edge, with no support for the back and in a very strained and fatiguing position. The equipment—the cashier's stamp, the carriers, crayon pencil, etc.—was also studied.

### Record of Work Done

The work done in handling a tube-room transaction was recorded by means of a process chart, a portion of which is shown in Fig. 2. The entire process was recorded from the point at which the sales clerk writes the sales check and receives the money from the customer, and the transaction is followed through the

work done by the merchandise checker and sales clerk until the change and package are handed to the customer.[4] The complete process was thus charted in order to avoid the danger of later making changes in the cashier's work which would interfere with the work preceding or following the cashier's operations.

The operations most directly relating to change making, that is, the operations of the cashiers, were studied more closely by means of the micromotion film.

Motion pictures were taken of five cashiers. In order to determine which cashiers were to be filmed, the motions of all cashiers were observed and the psychological factors influencing their work were considered, as well as their production over a period of six months. All of these factors were considered in deciding upon the cashiers to study, and therefore the cashiers studied were not necessarily those with the highest production or the speediest motions, unless at the same time their motions were obviously good or particularly interesting.[5]

The films were carefully analyzed both as to the motions used by the individual cashiers and also as to the relation of the work-

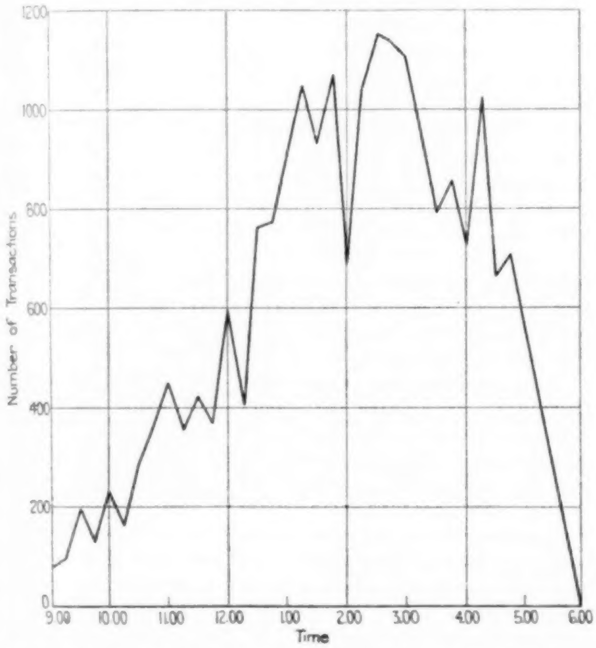

Fig. 4 Hourly Number of Transactions in "B" Tube Room—Saturday, March 26, 1927

place layout and the tools to the motions and variables of the cashiers. The cycles or complete transactions which showed differences in method, the use of fewer or more therbligs, the variables in the work, etc., were analyzed on simo charts. Twenty or more simo charts were made, one of which is shown in Fig. 3. Since different colors indicate the different therbligs, the different charts show clearly the variations in the therbligs used and also in the length of time spent on each therblig.

[4] [The process chart prepared by the authors and presented by them at the time the paper was read contained the complete data of the entire process. It is too large to be reproduced satisfactorily. Fig. 2 contains only that part of the chart which applies to the cashier's activities and only enough of these are shown to give an idea of how the chart is made and what it contains.—Editor.]

[5] [On the occasion of the presentation of this paper, the authors showed the motion pictures of the "present" and the "improved" methods. Some sections of these films are included on the process chart of Fig. 2 and show the clock from which the time elements were taken when the simo charts (Fig. 3) were made.—Editor.]

### Other Data Relating to Work

Other data relating to the cashiering work included information on the flow of business in the tube rooms. Figs. 4, 5, and 6 show the peaks in the tube-room business. Statistical data on the cost of operations of the tube rooms were also studied. Time studies were made of the cashiers to find the average time required per transaction, and, from the customer's point of view, studies were made on the selling floor of the time required to get change. These data were collected in order to have all data bearing upon the situation which were essential for complete analysis, as well as records of the "present" situation, so that

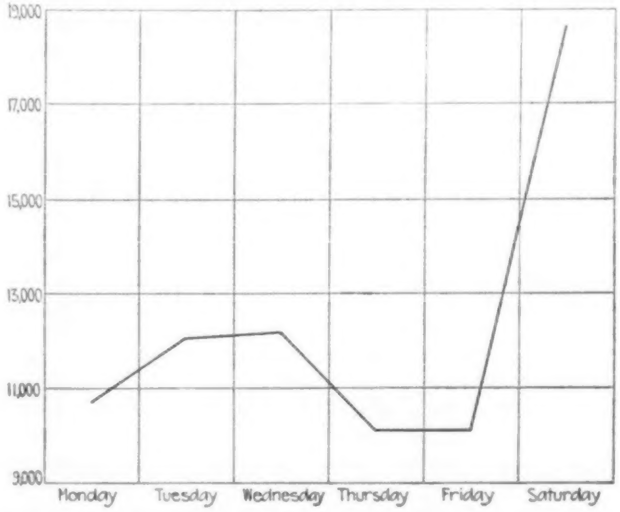

Fig. 5 Total Number of Transactions in "B" Tube Room—March 21 to 26, 1927

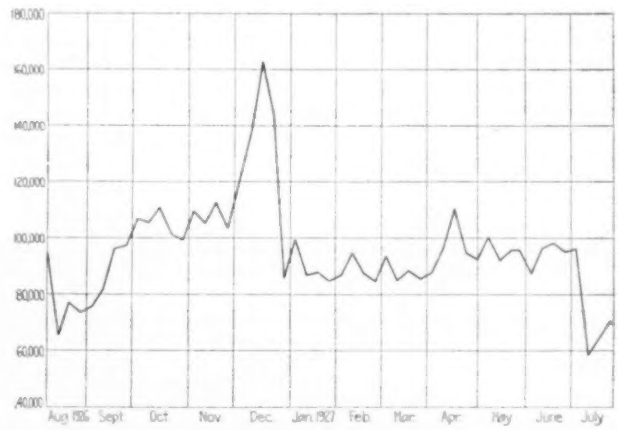

Fig. 6 Weekly Total Transactions Handled in Basement Tube Room—August 1, 1926, to July 31, 1927

comparisons could be made after changes had been determined upon and installed.

### Physical and Psychological Analysis

Each cashier was given a physical examination and various psychological intelligence and performance tests. A psychiatric analysis was also made, including personality traits, home conditions, schooling and training, age, etc., to discover the factors tending to affect the success of the cashier in this kind of work.

### Analysis of Present Practice and Improvements

All data on present conditions, methods, and workers were

then analyzed with the cooperation of the supervisors of the tube rooms and the cashiers themselves, all of whom considered the findings and the suggested change. Possible changes in the tube-room methods were considered in relation to the effect on the elements of the operation preceding and following.

For example, an analysis of the simo charts showed that from 27 to 34 per cent of the total time required to handle a transaction was required to write on and stamp the sales check. The cashier, as already explained, checked the extensions and additions of the sales check. After doing this she had to write the total amount of the sale on both copies of the sales check, the theory being that from a psychological point of view the cashier was forced to observe the amount of the sale carefully,

Fig. 7 Comparison of Old and New Cashier's Desks

and also that, in cases of dispute with the selling floor or the audit as to the amount of change given, the cashier's notation on the sales check would prove her interpretation of the sales check. The question then arose: Even so, was this writing necessary? And if so, was it necessary to write the amount on both copies of the sales check? After investigation, it was decided to retain the writing on one copy of the sales check only, but to eliminate it from the other copy.

Analyzing the methods of writing, it was found that one cashier held her pencil throughout the transaction, whereas all the others dropped theirs after the writing in one cycle and picked it up again when ready to write in the next cycle. The simo charts showed that the cashier who held her pencil used fewer therbligs at this point, and also that these therbligs which were eliminated helped her to perform this part of the transaction much more quickly than the other cashiers could. In fact, in some cases the pencil dropped back into the bill tills and then a "search" therblig was necessary in addition to a longer "transport empty" and "transport loaded," and to the "grasp" therblig. Experimenting with one cashier who had otherwise worked out excellent motions for herself, it was proved that after she had broken her habit of dropping the pencil and had established the new habit, her time for the operation was reduced, and that holding the pencil through the rest of the cycle did not prove a hindrance.

Two particularly bad features were obvious in the layout of the desk. First, the box in which the cashier put the copy of the sales check which she retained was at the upper left-hand corner of the desk. The cashier stamped both copies of the sales check with the stamp, located on the lower right-hand corner of the desk, and then carried her copy of the sales check to the box, diagonally across the desk, the longest distance. It was desirable to keep the stamp on the right-hand side for ease in stamping with the right hand, but the sales-check box was relocated directly under the stamp so that one copy of the sales check is dropped into the box as it is withdrawn from the stamp. Eliminating this long "transport loaded" and "transport empty" in the cycle reduced fatigue.

Another improvement in the desk was the relocation of the dispatch tube which had been behind the desk at the side next to the belt, so that the cashier had to turn partly around to reach it easily. Also, the mouth of the tube was very little larger than the carrier so that the carrier had to be positioned very carefully when dispatching it. The dispatch tube was relocated in the center of the desk but toward the side toward the belt, and a bell hopper was placed at the opening so that the cashier could throw the carrier in with practically no positioning. Fig. 7 shows the layout of the old and new desks.

The new desks were made 36 in. high with a comfortable foot rest at the bottom, and a work chair with a double saddle seat and adequate back support both for working and for resting was provided. With this equipment, the cashier easily alternates standing and sitting to reduce fatigue and the work place is equally convenient for both.

A locking device was also adopted so that the cashier no longer has to pack up her money and take it to the office every time she leaves her desk. This device has reduced the "get ready" time.

Improvements were also made in the surrounding conditions. The desk lights were removed, and greater general illumination was obtained by installing larger fixtures of the proper type at regular intervals, thus providing an even distribution of light with a minimum of shadows. An average uniform illumination of 18 foot-candles was provided. Noise was lessened by covering the drums and air tubes with felt padding and the walls with acousticon. Ventilation in one tube room was improved by installing screens, and the vibrations in the tube room directly over the engine room were reduced materially by supporting the lines from the floor of the engine room instead of from the ceiling under the tube room.

Rest pauses were also considered, and definite rest periods in the morning and afternoon were encouraged during busy periods. Separate rest rooms were established next to each tube room, so that cashiers could relax completely without traveling a long distance to and from the regular employees' rest room.

Other improvements were possible, but were not installed because of certain limiting factors.

## Setting Task and Incentives

Ordinarily, the next step in such a study as this would be to

set the task. This is determined by the times obtained from the micromotion study, augmented by continuous-production studies made over a whole day, or representative parts of the day, to get complete information on rest pauses and delays. The task would then be set on the basis of these times and the flow of work, and an incentive plan would be developed.

In this case, however, a standard of production and a bonus plan had been in operation for years. Since rate cutting is not consistent with the company's policy, it was decided not to change the task and the incentive plan, even though changed methods would make greater production possible with the same amount of effort.

### Selection and Training of Workers

The establishment of the best method of doing cashiering made it possible for the psychological and psychiatric department to develop a definite technique for employing new persons who would make successful cashiers. Using the definite and complete analysis of the job with the degree of success of the individual cashiers as criteria, the conference office of the employment department has been able to work up standards for age and schooling, and for physical, psychological, and psychiatric qualities.

Job specifications have been worked up for interviewers which give a brief but graphic description of the job and its functions, and which also include the personnel qualifications worked up by the conference office. For the applicant, there have been prepared descriptions of the job from the employee's point of view, the nature of the job, its relation to the rest of the store, the working conditions, the task-and-bonus plan, and the promotional opportunities.

The department of training has also found it much more satisfactory to use definite motions in training cashiers. The equipment of the tube room has been duplicated in the classroom—the same desks, chairs, etc., although the belt used here does not move. Real money has been substituted for theatrical money previously used in order to give definite training in handling coins and in mental arithmetic. From the first, the motions of the simo chart are used by the cashiers as the instruction card. Thus correct habits of motion are formed from the beginning.

### Results of Study

This study of cashiering has benefited the customers, the store, and the employees.

The result from the customer's point of view is that the service has been improved 26 per cent on the average. The present time required by the cashier is 17 per cent lower than the previous time of the best cashier, and 40 per cent lower than the poorest of a selected group of good cashiers.

From the point of view of the store, the study has resulted in a reduction in operating expense. Previous to the time of the study the average production of the cashiers was falling off, but since the better methods were determined the average production has increased. The table below compares average production in 1924, before these changes were made, with that in 1926.

| | 1924 | 1926 | Per cent increase |
|---|---|---|---|
| Full-time cashiers......... | 543 | 682 | 25.6 |
| Part-time cashiers......... | 362 | 434 | 19.9 |

The individual production of a cashier has increased. On the busiest day in 1924, the Saturday before Christmas, before the study, the best cashier had handled 2220 transactions. In 1925 the number had increased to 2738.

Another important fact which has made the tube-room operation less expensive since the study is that a shorter time is now required for the new cashiers to get up to standard production due to the improved selection and training methods.

To the cashier herself the new method has proved advantageous also. For example, higher bonuses have been earned: during the first December after the bonus was introduced, the total bonus earnings increased 88 per cent, over the December of the year before, and 44 per cent more cashiers earned a bonus, although the number of cashiers had not increased. The cashiers are now better adapted to their jobs. Moreover they are interested in the amount of skill they can develop and consequently find their jobs much more satisfying. And most important, much fatigue has been eliminated, so that the cashier is able to do more work without additional fatigue. This elimination of fatigue has resulted, as described above, from eliminating waste motions and by doing the necessary motions in the best way, and also by improving the surroundings and posture of the cashier.

# An Application of Motion Study to Group Work in Industry MAN-50-17B

By JOS. A. PIACITELLI,[1] NEW YORK, N. Y.

THE SUBJECT of motion study has been so thoroughly covered in the paper[2] by Miss Lies and Miss Sealy that it is hardly necessary to discuss further its principles. However, some of the points may be emphasized and there may be added a discussion of the analysis of work in general, mentioning briefly some of the major differences in the various techniques and pointing out some of the limitations under which the analyst must work when making a study of an operation.

The methods of study commonly known today may be grouped into two classes. Time study and operation study will fall into one, and micromotion study and time and motion study into the other of these classes. For convenience these two classes will be referred to hereafter as time study and motion study. The chief differences in them are in the manner in which the observations are made. When employing the time-study technique the analyst must make all observations relative to methods and general layout of equipment and tools with the naked eye. Using this technique, time records are made by standardizing the method and then breaking it up into subdivisions suitable for stop-watch observation, and finally the time for each subdivision is observed and recorded. With the motion-study technique a simultaneous record of the method and time as well as the layout of equipment, machinery, and tools is made with a motion-picture film and a Gilbreth clock. Advance standardization of method is not necessary in this case, for standardization

[1] Assoc-Mem. A.S.M.E.

[2] See paper no. MAN-50-17.

Contributed by the Management Division and presented at a meeting, New York, N. Y., January 30, 1928, of the Metropolitan Section of The American Society of Mechanical Engineers.

follows the establishment of the best method, which itself is the result of investigation. In the time-study technique the time element is considered the most important factor toward the solution, while with motion study the major contribution to the solution is expected from the analysis of the method. However, it must be remembered that, regardless of the technique employed, both the time and the method must be considered to obtain satisfactory results.

The characteristics of the work to be analyzed play an important part when determining the technique to be employed. There are jobs in which the percentage of handling time to the total cycle time is very small, and it is then most important to study closely the performance of the machinery employed. In operations consisting largely of handling work, and especially those highly repetitive, the motions made by the worker must be analyzed in order to establish the best method before any attempt at standardization is made.

The analyst using the stop watch must often work under limitations which make it impossible for him to get detailed and accurate data. A time study can be made with a stop watch only as long as the elements into which the job is divided are performed in sufficient time to permit the reading and recording of time data. But when short-cycle operations are studied and the elements on which time data are desired are performed in a few seconds, the task of making a usable record becomes rather difficult. Because of the error involved in the stop-watch readings it is usually difficult to time sub-operations lasting less than two seconds, and even more difficult to observe accurately and simultaneously the method employed during any one period timed. The motion-picture and Gilbreth-clock method not only makes the simultaneous observation practical, but reduces that part of the analyst's work to a comparatively simple procedure.

For example, for the purpose of studying a winding operation and establishing a more economical method of winding and handling rolls of felt, a motion-picture film was made. The crew consisted of a winder, a cutter, a helper, and a scale man, and it was possible to get data pertaining to methods and time of the four men in two scenes. A roll of saturated felt 74 in. wide was wound on the machine equipped with one winding mandrel and was cut off from the continuous sheet by the cutter. It was then transported with the mandrel still in its core to a tying table about six feet away by the winder, cutter, and helper. The mandrel was taken out of the roll by these men and transported back to its bearings on the machine. The winding of another roll was started by the three men, who simultaneously grasped the saturated felt sheet, passed it around the mandrel, and tucked its end between the sheet and the side of the mandrel. The expansion of the mandrel was performed by the winder and accomplished by turning an expanding nut on the end of the mandrel with a spanner wrench. As soon as this was done the machine was ready to wind the next roll. Starting and stopping of the machine were effected by the operation of a rheostat controlled by the winder, who was required to move to the side of the machine to do it. When the roll was wound to full length the winding was stopped by collapsing the mandrel after the power had been shut off but while it was still in motion. The roll was then cut off and removed from the machine and the cycle repeated.

When placed on the tying table the roll was tied with two pieces of muslin tape, to prevent unwinding, by the scale man, whose other duties consisted of tipping the roll off the tying table on to a scale, weighing and marking the weight on it, and again tipping it on to a roller conveyor which loaded it inside of a box car stopped alongside the door. As a matter of production and shipping record this man was also required to make note of the weight of each roll.

As a preliminary analysis, a process chart[3] was made of the simultaneous activities of these men, showing as accurately as it was possible to observe with the naked eye, what they did and how they did it. To those who were familiar with the operation many suggestions for improvement were obvious, but without time data of the elements of motion involved in the various sub-operations, it was not easy to rearrange the work to the best productive advantage nor to attempt to set a standard of performance in accordance with the possible new methods.

The film was taken and the time and method data for a selected cycle were put in form of visual records called "simo" charts. These charts made it possible to visualize the duration and sequence of each element of motion (therblig) in the complete cycle as performed by each hand of the operators, as well as any other useful activity of the body. The men interested, such as foremen, superintendents, and other engineers, were given the opportunity to analyze the work as represented on the charts and many useful suggestions toward lessening the fatigue and reducing cycle time were made by them.

Time does not permit the enumeration of all of the various changes made, but some of them should be noted. The reduction of the distance through which the roll and mandrel, weighing approximately 200 lb., had to be transported after they were taken off the machine, and the changing of the relative heights of the machine and tying and weighing table are a few of the changes which made the services of the helper unnecessary. In the old method three men were required to walk several steps with the load, while at present the roll and mandrel are moved the required distance by two men with a swing of the body and with less effort.

The comparatively long period of unavoidable delay during the winding process in the operating cycle of the three men was reduced by rearranging their work so that with the use of two mandrels they could remove the mandrel from the last roll wound, transport it to the machine, and partially expand it while the winding of the next roll was in process. The rearrangement of the cycle of this new sequence was greatly facilitated by the availability of the method and time data on the simo charts. The new method was finally established and shown on a new-method simo chart, consisting of a synthesis of the past performances recorded, together with data from other sources, such as that estimated for motions for which time data were not available, or that taken of similar elements modified to suit new conditions.

The work of the scale man has been very much simplified and fatigue greatly reduced by arranging the delivery of rolls directly on to a roller conveyor mounted on the scale, thus ridding him of the heavy work. In fact the few operations now performed by him, such as adding one muslin tape around the roll instead of two, marking the weight on the roll and recording it on an adding machine instead of a production record, can be taken over by the winder and cutter without any appreciable increase of fatigue or loss of time. However, in view of the fact that these two men will have little or no time to relax and overcome the effects of fatigue caused by their work, it was considered desirable to relieve them of as much work as was possible and to offer an additional opportunity to rest by maintaining the scale man and making provision for the rotation of functions among the three. A standard of performance was set allowing them 50 per cent over the synthesized minimum time, for delays and fatigue.

In brief, the solution may be summarized as follows: The present crew of three men is producing 40 per cent more than the former crew of four. The work is now less fatiguing and the earnings of the men have been increased on an average of 8 per cent, while the average reduction in labor cost is 42 per cent.

MAN-50-18

# The Work Required to Operate Several Makes of Typewriters

By F. H. Norton,[1] Cambridge, Mass.

*This paper reports a series of carefully conducted tests made on five standard typewriters, manufactured by different companies and bought at retail stores, to determine the amount of work required for their operation.*

*To eliminate the human element and to make it possible to measure the work involved, the typewriters were operated pneumatically by a specially designed apparatus which also recorded on a photographic film a curve whose integrated area was proportional to the work. After mechanical operation had been adjusted so that it simulated satisfactorily manual operation, and after a careful calibration of the instruments and apparatus, tests were conducted on the operation of the following parts: the type keys, space bar, capital shift, line space, and carriage return. Tables of results show that a given typewriter may be superior to others, from the point of view of work required for operation, for one of these operations, and inferior to some other for another operation.*

*In order to interpret these results in combination, all of these five operations being necessary in varying degree in ordinary operation, 25 typical business letters were analyzed to determine the average number of times each operation was performed. It was then possible to determine the total work to type the average letter on each of the typewriters, and a table of these results is given.*

*In a summary of the results, it is pointed out that certain elements which are independent of the actual work of operating the typewriter but which seriously affect fatigue are not covered by the investigation. Recommendations are made as to adjustment and servicing of typewriters.*

The purpose of this investigation was the careful measurement of the amount of work required to operate various makes of typewriters. More specifically it was desired to find the work expended in the normal operation of the type keys, space bar, capital shift, line space, and carriage return for several machines of each make; to find the average number of times each of these operations occurred in a representative business letter; and from these figures to compute the amount of work required to type the average letter on each make of machine.

## Selection of the Typewriters

The typewriters used in this investigation were of five standard American makes. They were purchased with cash and without previous notice from their respective agencies in several different cities, and were carefully transported by automobile to Cambridge. The agents had no way of knowing that these machines were being purchased for the purpose of tests.

All of the machines were stated by the venders to be new machines, properly adjusted. No adjustments or alterations of any kind were made on the machines after purchase. The substitution of the special uniform platens for the regular platens was only made after all other measurements on type keys, space bar, capital shift, line space, and carriage return had been made. One make of machine regularly has supplied interchangeable platens of varying hardness. In this case the platen was selected which had a hardness nearest the mean of those supplied for the other makes. Throughout this report the makes of typewriters will be known as A, B, C, D, and E.

[1] Rogers Laboratory of Physics, Massachusetts Institute of Technology.

## Work Required by Type Keys

The precise determination of the work expended in operating a key is a rather difficult problem because the motion is rapid and the light moving parts must have no appreciable mass added to them. There seemed to be no possibility of constructing a sufficiently light recording pressure dynamometer for attachment to the key. The only possible method appeared to be rather complicated but fundamentally sound. This consisted of measuring the motion of the key when a typist operated it in the usual manner; and then constructing a mechanism which would reproduce this motion and at the same time record the pressure exerted throughout the stroke. As the movement of the key is the same in both cases, the work performed by the typist in pressing the key must be equivalent to the mean effective pressure

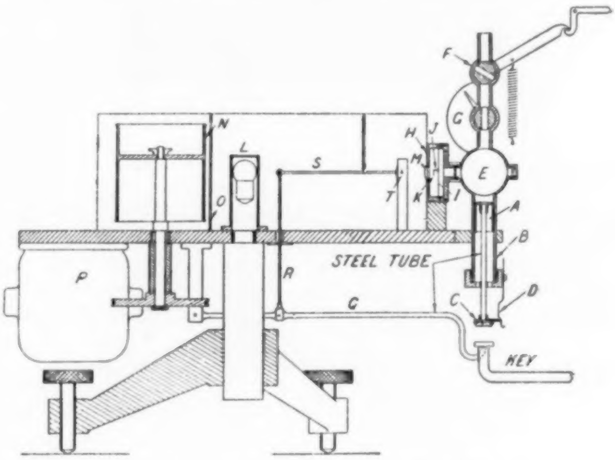

Fig. 1 Apparatus for Operating Type Keys

measured during the similar mechanical stroke, multiplied by the length of the stroke.

## Description of the Apparatus

The apparatus constructed for operating the key is shown in Fig. 1. The piston $A$ sliding in the cylinder $B$ operates through a piston rod, the felt covered disk $C$ which depresses the typewriter key. This disk can be initially held at any fixed height above the key by the stop $D$ which is so delicately adjusted as to offer practically no resistance to the piston movement. The piston was carefully lapped into the cylinder and an oil seal was provided by several narrow grooves cut around the piston. All the moving parts were kept very light so that their mass would be a small fraction of the mass of the key and its attached mechanism.

The piston is operated by admitting compressed air into the reservoir $E$ above the cylinder. In order that air should be introduced into the reservoir suddenly and in exactly the same way under like conditions, the spring-operated valve $F$ is used. This stopcock is held shut with a trigger and opened suddenly by a strong spring. In addition there is a graduated throttle valve $G$ to vary the rate at which air is introduced.

Connected directly to the reservoir by a short and relatively large passage (to eliminate any distortion of the pressure wave) is the high-frequency manometer *H*. This instrument is similar to the manometers used for pressure-distribution work on airplanes and airships. It has a natural frequency of about 300 vibrations per second, a constant calibration, a small temperature coefficient, and is not affected by vibration. The manometer consists of the diaphragm *I* with the stylus *J* attached to the center. The hardened tip of the stylus rests against the back of the stainless-steel mirror *K* which is mounted on pivots and held against the stylus by a watch hairspring. Therefore a slight movement of the diaphragm gives a considerable rotation to the mirror. Adjustments are provided for readily changing the zero setting or the sensitivity.

Light from the lamp bulb *L* passes through the lens *M* on to the mirror *K* and is reflected back through the same lens and focused on the film *N*. A slit *O* gives a point image on the film. The film, which is wound on a drum, is moved at a constant angular velocity by the motor *P* through suitable reduction gearing.

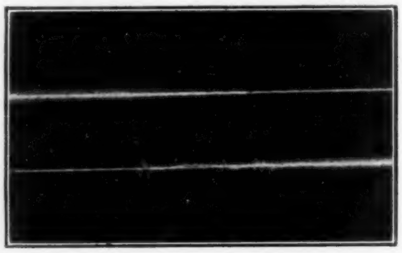

Fig. 2 Pressure Curves

This instrument makes records of the size shown in Fig. 2. The range of pressure as adjusted for this work is about 50 cm. of mercury. The recorded trace is so sharp that the record can be enlarged and read with much greater precision than is required here.

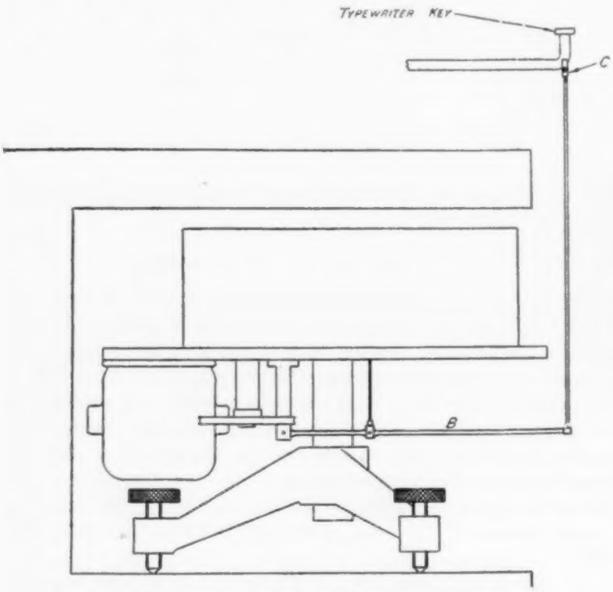

Fig. 3 Apparatus for Measuring Key Deflection

The movement of the key is recorded by a mechanism also shown in Fig. 1. The lever *Q* rests underneath the key and is pivoted at the back end. The link *R* connects it to a second lever *S* pivoted at *T*. On this pivot and behind a lens is a small mirror which reflects light from the lamp *L* on to the film. This allows the simultaneous recording of pressure and deflection.

When it is desired to record the key motion under manual operation, the set-up in Fig. 3 is used. The instrument previously described is placed upon a solid support under and at one side of the typewriter. A light strut *A* connects the lever *B* with the key through the fitting *C*. A record can be taken of the motion of any key, and the operator need not know which key is connected.

The air pressure supplied to the instrument is obtained from a tank of about 6 cu. ft. capacity which may be pumped up with a tire pump. The tank pressure is measured by a mercury manometer in the usual way. The system was tight enough to hold a substantially constant pressure for several days.

Fig. 4 Assembly for Obtaining Operator's Curve

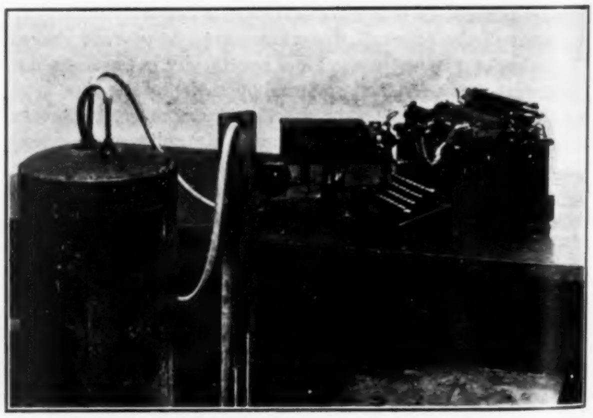

Fig. 5 Assembly for Duplication of Operator's Curve

## Calibration of Apparatus

The recording manometer on the instrument was calibrated by connecting it directly to the tank and taking a number of records with several known and constant tank pressures. The film records were measured and the distance of each recorded pressure line above the zero was plotted against the tank pressures.

It should be mentioned here that all of the films were measured by placing them in a projection lantern and tracing them off to a

large but constant scale on a sheet of paper. This method was rapid and saved eye strain, which was important when it is considered that more than 2000 records were taken in developing the apparatus.

The record of the key deflection was standardized by depressing the key with a micrometer screw and taking records at frequent intervals. The resultant curve of key deflection plotted against the motion of the spot of light across the film was a straight line. This gives a constant factor by which to multiply the distance on the film in order to get the key travel. This factor was 1.24 for the short lever of Fig. 1, and 1.20 for the long lever of Fig. 3.

Figs. 4, 5, and 6 show general views of the apparatus and give a good idea of the construction and method of operation.

Fig. 6 Assembly for Obtaining Impression Tests

### Key Motion With Manual Operation

A large number of records were made to show the key motion. These records brought out the following facts:

(a) A given operator does not exactly duplicate the record on successive trials.

(b) There is no great difference between records made by the several typists.

A number of operator's type-key-displacement records are shown in Fig. 7 to illustrate the points. From many data of this kind it was thought permissible to use the same skilled typist on all makes of machines, as this procedure in the end would give more strictly comparable results.

### Key Motion With Mechanical Operation

The next problem was to so adjust the pressure cylinder as to reproduce the preceding key motions. The following adjustments could be made:

(a) Air pressure
(b) Throttle-valve position
(c) Initial height of the pad above the key
(d) Softness of the pad
(e) Lower limit of piston travel
(f) Mass of the moving parts.

It is believed unnecessary to go into the details of the adjustments made. After some experimenting practically any hand operator's curve could be reproduced. An example is shown in Fig. 8. It was shown later that a considerable change in the

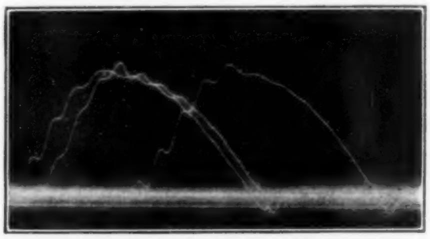

Fig. 7a

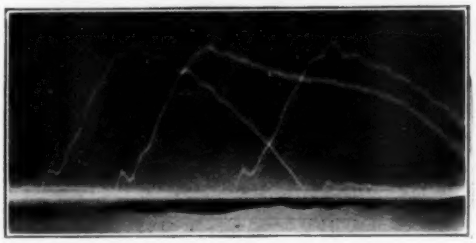

Fig. 7b

Fig. 7c

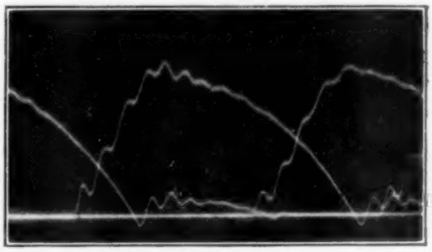

Fig. 7d

Figs. 7a and 7b Two Operators on the Same Machine and Same Key

Figs. 7c and 7d Single Operator on Hard and Easy Action

shape of the curve for a given tank pressure will have little effect on the type impression on the paper.

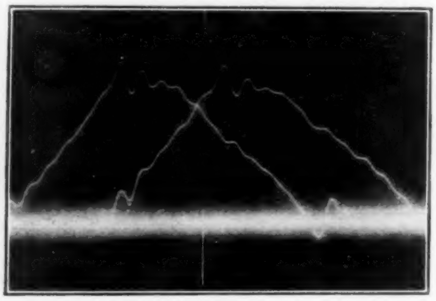
Now that it is certain that the manual motion of the key can be reproduced mechanically, the pressure curves taken simultaneously with the displacement curves are of chief importance.

In Fig. 9 are shown simultaneous pressure and displacement curves redrawn from the original of a typical record, to give a larger scale. It will be noted that the pressure rises very rap-

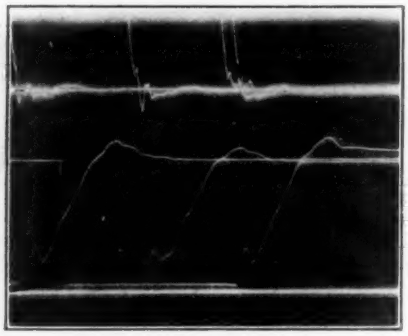
idly—in 0.0005 sec.—and, except for a slight surging on reaching the maximum, remains constant for the remainder of the stroke.

The work accomplished during the stroke is evidently equal to the mean effective pressure during the stroke multiplied by the length of the stroke and the piston area. This is the same condition occurring in engines and needs no further explanation. We have only to define the stroke and mean effective pressure.

Referring to Fig. 9, the stroke is given as the distance $L$, and the time by $t$, and the mean effective pressure by the shaded area divided by $t$. As the pressure on the piston is equal to the tank pressure for much of the stroke, it might be expected, that there would be a constant relation between the tank pressure and the mean effective pressure. Could this relation be established, a great deal of time would be saved as a pressure record would not have to be taken and measured for each stroke.



Mechanical



Manual

Fig. 8 Reproduction of Operator's Curves

(The difference in height of curves is due to difference in length of magnification arm of the instrument. The oscillation shown in all curves is due to the elasticity of the key levers.)

A number of records were made on the easiest- and hardest-working machines at different pressures with the instrument assembled for operating keys, space bar, capital shift, line space, and carriage return. The mean effective pressure for each case was computed from the planimetered area under the pressure curve. The mean effective pressure thus found is plotted against the corresponding tank pressure in Fig. 10. As expected, the points fall closely on a straight line up to a pressure of 35 centimeters of mercury. Above this the points depart sharply from the line which is undoubtedly caused by the forcing of the oil out of the piston grooves at this pressure. This is confirmed by the commencement of hissing when the pressure reaches this value. The use of a heavier oil would raise this critical pressure, but as it is above the range used in these tests no change was deemed necessary.

The slope of the curve in Fig. 10 gives the factor by which to multiply the tank pressure in order to obtain the mean effective pressure. The work is given by

$$W = APKdgL$$

where

$W$ = work in ergs
$A$ = piston area, here = 1.292 sq. cm.
$P$ = tank pressure in cm. of mercury
$K$ = constant to convert tank pressure to mean effective pressure = 0.97
$d$ = density of mercury = 13.6 grams per cc.
$g$ = acceleration of gravity = 980 cm. per sec.
$L$ = length of the stroke in cm.

### Comparison of the Impressions

Now that it is possible to obtain the work for a given key stroke, it is necessary to be able to duplicate the effectiveness of the stroke on all machines. This was done by using in all tests pieces of ribbon from a lightly inked ribbon 144 yards long obtained from a well-known manufacturer. Sheets of paper were used from the same package. Then by making typewritten records on each machine at a number of tank pressures, the pressure giving the nearest approach to a standard could be selected. In all such impression tests two carbon copies were made.

The selection of the tank pressures giving equal impressions is the least precise part of this investigation. By carefully examining the impressions of a number of letters in the standard and on the test sheet with a magnifying glass, two independent observers are almost always able to check each other within a pressure of one centimeter of mercury. It does not seem possible to obtain a greater precision than this because of irregularities in type, paper, and ribbon, and because of the uncertainty of matching impressions by the eye. However, this gives a precision of from 3 to 5 per cent for a single machine.

It was believed that the hardness of the platens might vary between the different makes of machines and partially account for the differences in work required to make a standard impression. A hard platen would undoubtedly require less work to produce a given impression than a soft platen. After all other tests had been completed on the machines, special uniform rolls, made up by turning about 2 mm. from the diameter of the regular platen and forcing on a brass tube of the original diameter, were substituted for the regular platens. The pressure was determined that would give a standard impression. In all cases the pressures were lower, but the comparison was made difficult because of the irregularity of the impressions made on the special uniform platen.

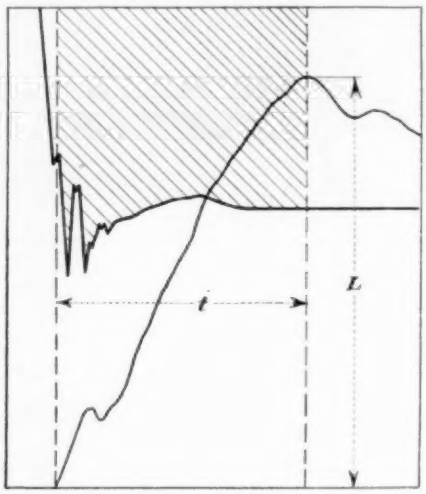


Fig. 9 Enlarged Pressure-Displacement Record

### Method of Making Tests on Type Keys

Each typewriter was tested by placing the air cylinder directly over the key and raising the piston to the proper height. Two carbons and three sheets of paper were placed in the machine. The tank was pumped up to the desired pressure, the trigger released, and the impression made. This procedure was repeated for all the letters across the second row from the bottom, at the same tank pressure. The tank pressure was then raised 1 cm. and another row of impressions made. These impressions were then compared with the standard in the manner previously described.

### Results on Type Keys

The results obtained for the type keys of the twenty-five machines tested are listed in Table 1.

On examining these results it will be noticed that there is a considerable variation in work between different makes of typewriters and a smaller variation between machines of the same make. While it is not within the scope of this report to analyze the motion of the typewriter mechanism, it is believed that most of this variation is due to the resistance offered by the carriage escapement. In fact, a small adjustment of the escapement spring will greatly alter the work required to operate the key.

In general the special uniform platen required about 0.7 of the work needed to give the same impression on the standard rubber platen.

The order of merit of the various machines in regard to type-key work is E, A, C, D, and B.

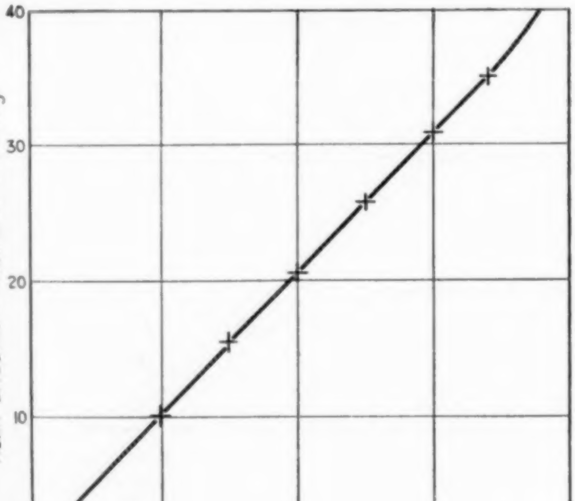

Fig. 10 Relation Between Mean Effective Pressure and Tank Pressure

It was also noticed that there is some variation in length of stroke. It should be kept in mind that the relative work required to operate the keys may not be a measure of the fatigue suffered by a typist. That is, of two machines requiring the same work, the one with a long, easy stroke might be less fatiguing than the one with a short stroke.

### Work Required by Space Bar

The method of obtaining the work necessary to operate the space bar was somewhat different from that used for the type keys because no impressions are made. The method finally used consisted in obtaining typical displacement curves for the space key on each make of typewriter when operated by a skilled typist. Displacement curves were then taken when the key was operated pneumatically, at several tank pressures. A curve was then plotted of tank pressure against the time taken for the stroke as measured from the enlarged curve in the way previously described. The pressure on this curve corresponding to the time taken for the stroke by the typist was the desired value. Curves of this kind are shown in Fig. 11.

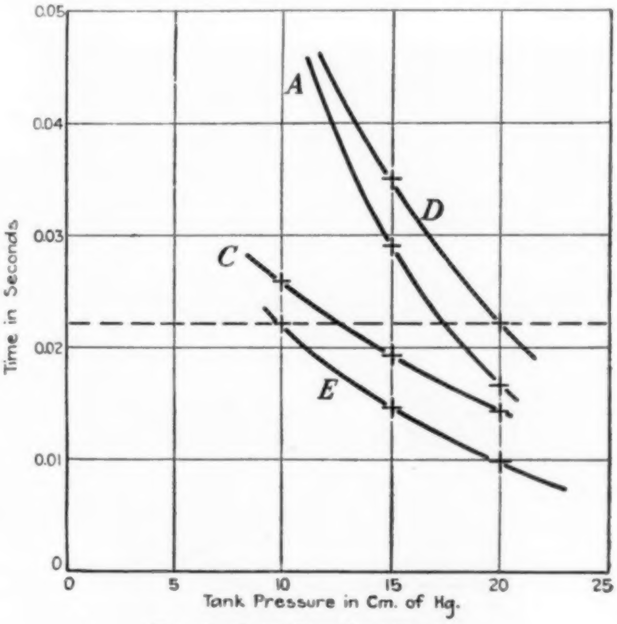

Fig. 11 Space-Bar Time Curves

The apparatus was the same as used for the type keys, but the operating pressure was considerably less.

### Space-Bar Motion

In Figs. 12*a* and 12*b* are shown several pressure-displacement curves for the space bar. They differ from the type-key records in having a shorter stroke and a definite stop. The average time required for the stroke was 0.0223 sec.

TABLE 1 WORK PER STROKE[1]

| Make | Type keys: Rubber platen | Type keys: Special uniform platen | Space bar | Capital shift | Line space | Carriage return |
|---|---|---|---|---|---|---|
| | 55 | 40 | 37 | 147 | 410 | 1100 |

[1] The work is expressed in ergs divided by 10,000.

As the same piston was used for the space bar and type keys, the same factor for converting the tank pressure to mean effective pressure was required. The work, as before, is calculated from the same equation as the type-key work.

### Results on the Space Bar

The results for the machines tested are given in Table 1.

The values of the work required by the space bars are about one-half of those for the type keys, due to the shorter stroke and lower resistance. It appears that there is little relation between the type-key and the space-bar work. For example, the machine which has the next to the lowest value for the type-key work had distinctly the greatest value for the space-bar work.

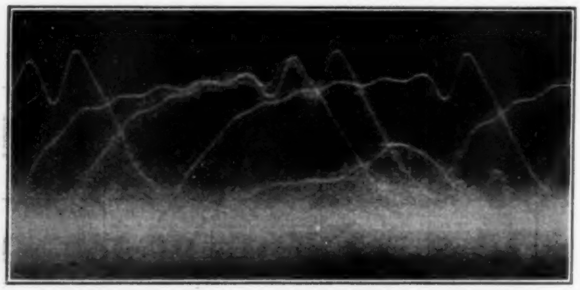

Fig. 12a Operator's Records of Space Bar

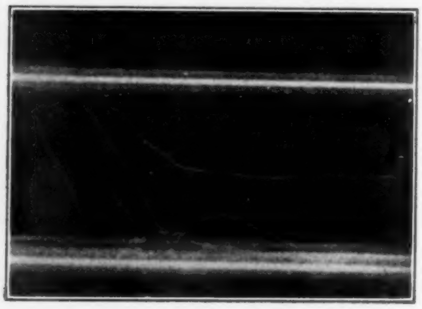

Fig. 12b Pressure-Operated Records of Space Bar

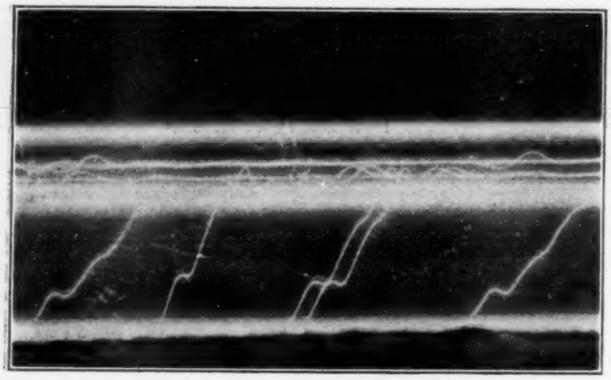

Fig. 13 Shift-Key Pressure-Displacement Records

The makes of machines may be rated in order of merit in regard to the work required by the space bar as follows: E, B, C, D, and A.

### Work Required to Operate Capital Shift

The force required to operate the capital shift was so much greater than that for the other keys that a pressure of 50 to 60 cm. of mercury was needed. A pressure of this magnitude blows the oil from the piston rings and causes a bad leak. For this reason a new cylinder and piston were constructed of twice the diameter of the previous one, but in all other respects the same.

The method of obtaining the work was identical with that used for the space bar. In Fig. 13 are shown a number of pressure-displacement records for the shift key. The time of stroke is comparatively long, averaging 0.067 sec. The lengthened time is due to the large mass that must be moved.

The work required to operate the shift key on the machine is given in Table 1. The work is computed from the same equation as for the space bar, in this case the area $A$ being 5.08 sq. cm. instead of 1.292 sq. cm. The constant $K$ is 0.97 as before, measurements having been made of planimetered pressure curves to determine this value.

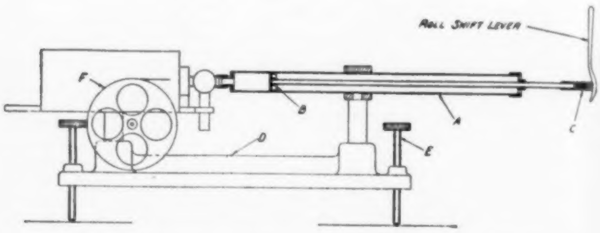

Fig. 14 Apparatus for Operation of Roll and Carriage

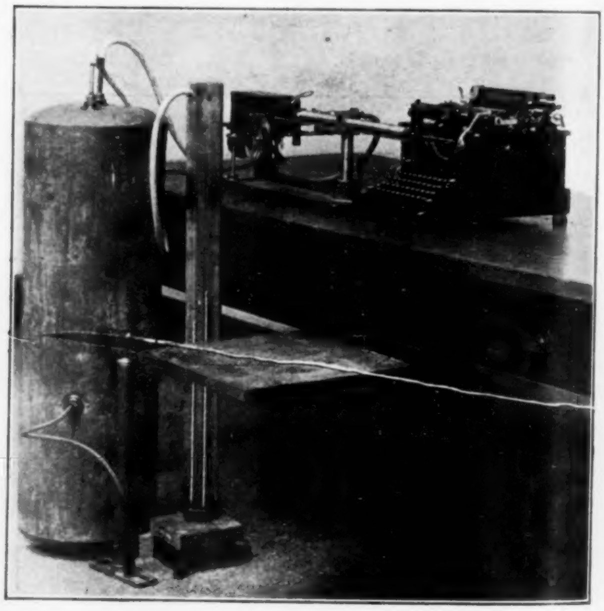

Fig. 15 Apparatus for Moving Line Space

The work required to operate the shift key is about three times as great as for the type key. There is about the same variation between machines as for the type keys. The order of merit is: C, E, and D the same, A, B.

### Work Required to Operate Line Space

The method of obtaining the work required to operate the roll was the same as used for the capital shift; the operator's time was reproduced mechanically and the work computed from the pressure and the stroke. The work was obtained for moving the roll a single space as this is used probably as much as a double space in letters, and serves as a simple comparison between machines.

The apparatus used for this test is shown in Figs. 14 and 15. The same air chamber, valves, and recording manometer are used as before, but a new cylinder *A* is provided in a horizontal position. The piston *B* forces the rod and finger *C* against the line-space handle. A heavy base *D* is provided with leveling screws *E* for vertical adjustment.

The motion of the line-space handle is recorded by attaching a piece of silk cord to it and running it around the large pulley *F*. This pulley is very light and is mounted on a small shaft. A fine cord wound on this shaft connects to the arm of the displacement mirror previously described.

Records were first taken on each make of machine when the line space was operated by a typist. From these records the time taken to complete the operation was measured as 0.0363 sec. The roll was then shifted mechanically at several pressures and a curve plotted as previously described for the space bar. In this way the pressure needed to reproduce the motion of the typist was obtained. A number of deflection curves are shown in Fig. 16, the motion being taken in the center of the hook on the line-space lever. The length of stroke was measured as the length of piston travel while the finger was in contact with the key. This was measured at the time of taking the records.

Table 1 gives the results of tests on the roll. The work was computed as before, the piston area being 5.08 sq. cm. and the constant *K* being again experimentally determined as 0.97.

The work necessary to operate the roll one space is considerably greater than that required to operate the keys. The order of merit of the makes of machines is as follows: D, B, E, C, and A.

### Work Required to Operate Carriage Return

The apparatus and method for determining the work to operate the carriage return were the same as for the line space. The stops were set to allow a motion of 66 spaces to represent a fairly long line. As the pressure was constant during the stroke it was assumed that the work required for shorter lines would be less in proportion to the length.

The records of Fig. 17 show some curves of carriage motion, and bring out clearly the relatively low velocity attained. The average operator's time for the carriage return of 66 spaces was 0.332 sec.

The data obtained and the computed values are summarized in Table 1. The calculations are based upon a 33-space return in accordance with values to be summarized in a later table.

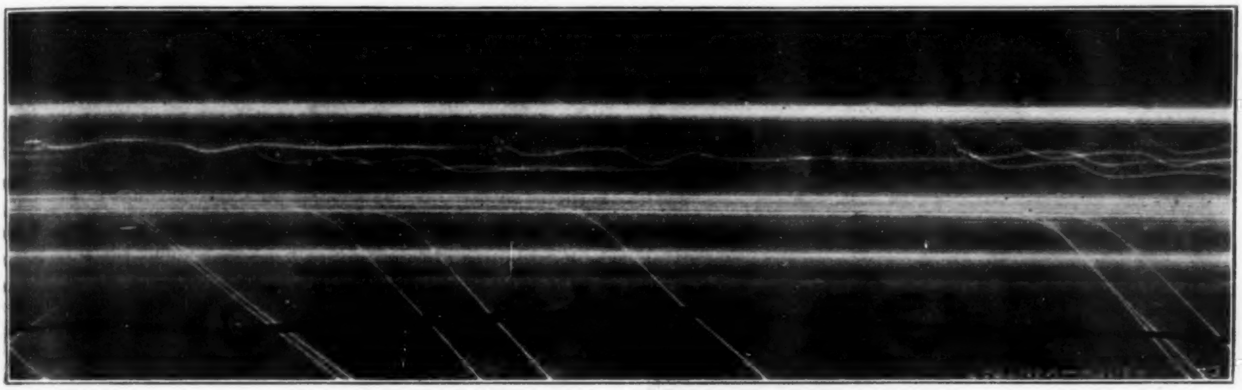

Fig. 16 Line-Space Deflection at Various Pressures
(Upper curves, pressure; lower curves, displacement.)

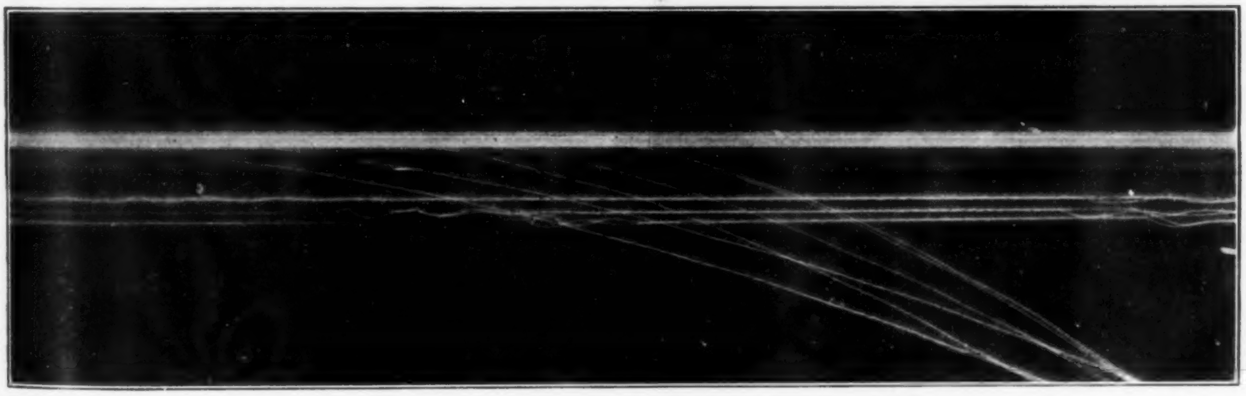

Fig. 17 Carriage-Shift Curves

The carriage requires a large amount of work for returning. However, a comparatively great uniformity of the values is shown, not only between machines of the same make but between different makes. This is probably due to the fact that the carriage spring tension can be accurately and permanently adjusted. The order of merit for carriage-return work is E, A, C, B, D.

### Analysis of Business Letters

Twenty-five letters were selected at random from a set of correspondence files with only the following limitations: (*a*) no two from the same correspondent, and (*b*) pica type.

These letters were analyzed by carefully counting the following characteristics of each letter, including the address on the envelope:

(a) The number of characters appearing, average 708

(b) The number of single spaces, counting no spaces longer than two consecutive single spaces, average 119

(c) The number of times the capital shift had been operated, average 38

(d) The number of single-spaced lines between the beginning and end of the letter, counting all untyped lines (for the roll motion), average 38

(e) The number of lines actually typed (for the carriage motion), average 25.

It is not claimed that the averages obtained here would be duplicated by selecting a second lot of 25 letters, but it is believed that the deviation would be so small that the additional labor involved in obtaining a more representative average would not be justified. At any rate the same figures are used for all makes of machines so that their comparison is not affected.

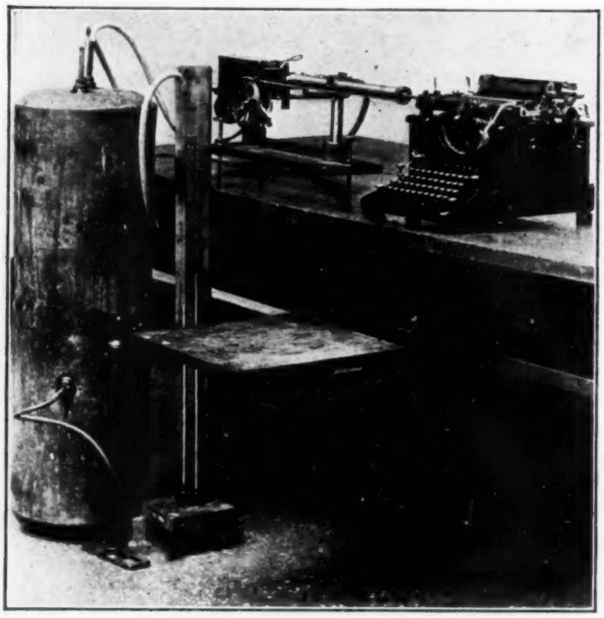

Fig. 18 Apparatus for Moving Carriage

## Total Work Required to Write the Average Letter

The sum of the amounts of work required for every operation on the typewriter multiplied by the number of times that the operation occurs in the average letter will give the total work used in writing the letter. These values are given in Table 2.

### Precision of Results

We may consider the precision of the work measurements both for the individual components and for the total. If we were interested only in the total work required to write the average letter, no component need be determined any closer than the one of least precision. An examination of the work shows that a majority of the total is made up of the type-key work and the carriage-return work. Therefore the remaining components need be determined with relatively less precision as their effect on the total is small.

However, as it was believed that considerable information could be obtained by a direct comparison of the separate components, they were all obtained with about the same percentage of accuracy.

The work of the type keys was obtained with a precision of ± 5 per cent; that is, different tests under the same conditions could be checked within this amount. The other components had a precision of from ± 3 to 5 per cent. The total work for the average letter should have a probable error somewhat less than that for each component, or around ± 3 per cent.

TABLE 2 TOTAL WORK TO TYPE AVERAGE LETTER[1]

| Make | Type keys: Rubber platen | Type keys: Special uniform platen | Space bar | Shift key | Line space | Carriage return | Total work: Rubber platen | Total work: Special uniform platen |

| | 46 | 32 | 3 | 4 | 15 | 37 | 105 | 91 |
| | 40 | 32 | 4 | 3 | 11 | 39 | 97 | 89 |
| Average | 45.2 | 32.0 | 3.6 | 4.2 | 10.8 | 35.8 | 100 | 87 |
| | 28 | 25 | 2 | 4 | 14 | 24 | 72 | 69 |
| | 32 | 25 | 3 | 4 | 11 | 26 | 76 | 69 |
| E | 28 | 23 | 3 | 4 | 20 | 30 | 85 | 80 |
| | 34 | 28 | 3 | 4 | 21 | 26 | 88 | 82 |
| | 27 | 21 | 3 | 5 | 18 | 30 | 83 | 77 |
| Average | 29.8 | 24.5 | 2.8 | 4.8 | 16.8 | 27.2 | 81 | 76 |

[1] All figures in this table should be multiplied by 10,000,000 to give work in ergs.

### Conclusions and Recommendations

These tests bring out strikingly the fact that a comparative test made on a single machine of each make would be entirely misleading. Undoubtedly an average of, say, ten machines would give a more representative set of values, but it would be rather unlikely that the relative order of the makes would be changed except possibly in the case of machines C and D.

The marked variability of the work required for different machines of the same make is rather surprising, and brings out clearly the lack of uniformity of adjustment. Again, some makes of machine will require the least amount of work for one of the operations, but no single make holds the advantage in all. If we select the least value for the work of each separate operation in Table 2 and add them, we obtain the figure 64, which is about 0.6 of the average value found for all machines. This brings out the practicability of greatly reducing the work required to write a letter.

The tests indicate clearly that every typewriter of each make should have a standardized factory adjustment. This adjustment should be carefully determined from a thorough study of the machine; and it should give the best compromise between ease of operation, speed, and durability. The typist should be given a machine adjusted for the most efficient operation, and this adjustment should not be changed because of individual inclinations. This would have the distinct advantage of operating under conditions of maximum efficiency and would allow a change from one machine to another without discomfort or extensive servicing. The local adjusters should be permitted only to check the factory adjustment, but not to alter it. In this way all machines would have the same operating characteristics—the best. This program could not perhaps be carried through abruptly, but should start in the schools and in a few years cover all machines used.

There is another aspect of this problem that should not be forgotten. This is the well-recognized physiological fact that work accomplished does not measure effort or fatigue, as a few examples will show. As indicated in Table 2, the work expended

on the keys is about equal to the work expended in returning the carriage, for the average letter; yet nearly every one will admit that it is more tiring to strike the keys 700 times than to move carriage 24 times. Again, the total work needed to type a letter is the same as the amount that would be required for the average person to step up one step on the stairs; and it is needless to say that the typing of 20 letters takes more physical effort than climbing one flight of stairs. This discrepancy between work accomplished and fatigue is mainly due to two things: the muscles not only expend their energy in performing external work, but also perform work in moving the parts of the body, such as the hands and fingers; and the more powerful muscles of the body perform a given amount of work with less fatigue than the weaker ones. This all leads to the conclusion that the work required to operate a typewriter is not an exact measure of physical effort. In the present tests, however, the operation on the different makes are so nearly alike that for comparative purposes the data given should be satisfactory from the point of view of fatigue as well as of work.

Acknowledgment

Practically all of the laboratory work for this investigation was carried out by Prof. L. H. Young of the Department of Physics at the Massachusetts Institute of Technology. The precision attained in these measurements is due to his careful and painstaking work in setting up and operating the special recording instruments used in this investigation.

# Progress in Materials Handling

## Contributed by the Materials-Handling Division

Executive Committee: R. H. McLain, *Chairman,* M. W. Potts, *Secretary,* J. A. Shepard, G. E. Hagemann, F. D. Campbell, and C. D. Bray

STURDY progress has been made during 1927 in the development of materials-handling equipment and in the application of that equipment to the needs of industrial plants, mines, construction, railroads, and marine carriers. While no outstanding advances are to be noted either in equipment design or use, there is no question but that the past year marks the active start of a transition period during which the business of materials handling will evolve from an empirical art into a scientific technique. Increasingly, profits, in materials handling must depend upon the precise fitting of equipment to the work to be done and to the coordination of the various handling units in a given installation in such manner that overall economies become maximum.

In the preparation of this report questionnaires have been circulated among several hundred concerns using materials-handling equipment, among practically all concerns whose business it is to design and to lay out plants, among representative builders of every recognized type of materials-handling equipment, among editors of representative industry publications, and among executive secretaries of industry associations. Equipment builders have been particularly helpful and have supplied your committee, not with propaganda, but with basic facts believed to be of value in recording progress of the year. Strangely, those concerns designing and specifying equipment for plants, both old and new, have failed to contribute anything whatever that is pertinent to this record. From each of the other groups questioned at least a few leaders have responded fully.

Approaching the subject first from the equipment point of view, we note that most developments have been in line with modern-equipment construction practice—whether for materials handling or for other purposes. Steel is coming into use in place of heavy castings, welding is supplanting riveting, simplification and exact machining for interchangeability of parts is becoming more common, improved bearing construction and better lubrication—these are basic trends.

With these developments in equipment, a better concept of the place of materials handling in production is reflected in—

1 Development of more effective organizations for materials handling, as at plants of the Otis Elevator Co., Westinghouse Electric & Manufacturing Co., Crompton & Knowles Loom Works, B. F. Goodrich Tire & Rubber Co., Hudson Motor Car Co., New York Central Railroad Shops—to mention but a few.

2 Building new plants around the transportation system rather than the transportation system around the plant—The Buick foundry, West Coast Porcelain plant, and A. O. Smith frame plant are cases in point.

As for particular developments in various types of materials-handling equipment, the following facts are significant.

### Cranes

Evidence of special effort to meet special conditions and requirements with an assembly of standard units built by quantity-production methods is notable. In addition to the general equipment trends noted above, that hold for cranes, the use of I-beams in place of expensive riveted box girders, the speeding up of light cranes, the reduction in size of electrical equipment and power drives, greater compactness of design securing lightness with strength, increased ease of operation, lubrication by oil baths and reservoirs abolishing the old grease cup—all of these changes are taking place. Crane manufacturers feel that users of this equipment should not be concerned with trick bearings, special limit switches, motors, and control apparatus which are being urged upon them by independent manufacturers not directly concerned with the building of materials-handling equipment.

Within the last six months another development is reported that is believed to open a big field for the effective use of crane equipment in wire mills. This is in connection with the cleaning house and baker. One company has developed a special cleaning-house crane with electrical equipment so arranged that acid and fumes from the acid cannot with any great degree attack the electrical equipment. This consists of a single-leg gantry crane with the motor located near the floor, and in connection with this scheme it is necessary to arrange the tubs in which the cleaning is done in what are called "straight" floors instead of circular floors with the old type of circular crane that is in use in practically all wire mills today. The first application of this device will shortly be made at the Bourne-Fuller Steel Company in Cleveland.

### Hoist and Tramrail Equipment

Fitting hoists and jib cranes to machine tools more extensively is considered significant. The installation of electrically controlled monorail switches at the Maytag Company's plant, representing a modification of an earlier installation at the Saco Lowell Shops, is considered by a firm of consultants in Detroit to be worthy of mention. The installation of remote-control equipment of this kind speeds up a monorail just as the automatic street-car switch, which is controlled by the motorman, speeded up the street car a few years ago. The use of electric hoists in connection with skid equipment moved by 10-ton-capacity electric trucks has made possible revolutionary changes in the method of handling sheet steel in and out of freight cars.

Proportional pressure control for brakes on large hoists used on mining machinery is reported to have been perfected during the year.

New applications of tramrail equipment are reported—as in the warehouse that arranges the split-package stock in the same order in which orders from the stores are written up. This is usually arranged up and down both sides of several aisles equipped with the tramrail system and with a rack adapted to take an ordinary warehouse truck. This truck is installed upon the rack, and three racks are hooked permanently in a train. The men filling orders walk along the aisles and the carriers are propelled by electricity along the rail at either 25 ft. per min. or 300 ft. per minute. The speed is fixed by means of push-button control.

A recent tramrail installation made at the plant of the Manchester Terminal Warehouse Company, Manchester, Texas, involves the use of 150 electrically propelled carriers that are sending four bales of cotton along the rail like a cash carrier

in a dry-goods store, eliminating the necessity of men traveling with each load. There are 17,000 ft. of rail involved on this system, and the rail is so arranged that there is no possibility of two carriers going in opposite directions colliding with each other, and it is also possible to get from any place in the receiving or shipping department and warehouse to any other place in the entire plant. This installation is causing considerable comment in the cotton warehouses of the South at the present time.

### Elevators

Increasingly, elevator equipment going into both old and new plants is being fitted to the transportation needs. Elevators capable of carrying a train of one electric tractor and 4 trailers to any floor of an 8-story building is typical of developments of this kind that are taking place. Micro drive for self-leveling elevators, while not a new development within the year, probably has won wider acceptance recently than ever before.

### Electric Industrial-Transportation Equipment

Storage-battery electric-truck manufacturers have widened equipment types available, and report an increasing sale of specially modified equipment engineered to meet precise service conditions. The use of live skids with lift trucks for handling freight in railroad l.c.l. service is reported to be on the increase. More high-capacity trucks are being built—from 5 to 10 tons—to meet the growing demand for the movement of heavier loads with fewer trips and hence with the expenditure of fewer man-hours. The Hudson Motor Car Co.'s materials-handling installation, around the use of 10-ton trucks, is pronounced by one disinterested authority to "excel what Ford has done." The perfection of the automatic coupler is another development of significance in connection with this type of equipment. This reduces personal injuries to workmen. In trailer design, aside from the new couplers, one definite development is the unit trailer employing a lifting device to raise reels of wire—holding them in the raised position during transport.

In the lift-truck field, a newcomer is noted in a unit to carry approximately 3000 lb., using a mechanical lifting mechanism actuated by the foot, while employing electric power in the usual manner of transport. This truck is designed to carry the 7-in. skid which has been developed for the older type of hand lift truck.

The most recent development by one company is an attachment to the crane truck. It consists of a heavy steel plate 30 in. wide, bent at an angle which is slightly acute and slidably mounted on a pair of steel channels which are attached at the upper end to the boom of the crane, and at the lower end to the coupler on the end of the truck. At the upper end of the steel plate and projecting from it is a curved plate-steel arm pivotably mounted. The hook of the crane cable is attached to the end of the arm nearest the steel plate which slides on the verticals. When the crane cable is wound up on its drum the strain raises the inner end of the arm and depresses the outer end so that it comes in contact with any article such as a roll of paper placed on the lower and horizontal portion of the bent plate, securely holding it in place while the plate slides up the vertical channels. By this simple device 1400-lb. rolls of newsprint paper are picked up where they have been landed on a pair of 2-in. × 6-in. planks placed just far enough apart to permit the horizontal portion of the bent plate to be inserted between them, and are carried to any point where the paper is to be stored. When lowered, the point of the bent plate touches the floor or a roll which has previously been placed. As soon as the tension on the crane cable is relieved a spring raises the arm, allowing this roll of paper to run down the bent plate and off into the position desired by the operator. By this means the truck operator, without assistance, can pick up, carry, and pile these awkward packages four high. When it is desired to use it as an ordinary elevating conveyor, the arm may be quickly removed and the crane cable attached directly to the end of the vertical portion of the bent plate. Means have been provided for adjusting the vertical members on which the bent plate slides so that various fixed angularities to the vertical may be obtained to suit varying commodities and conditions. In actual performance, ship's tackle raises two rolls at a draft. Two trucks equipped with cranes and paper-carrying attachments worked one hatch on a haul of about 350 ft. and less. The maximum performance was 104 rolls of paper per hour for the hatch, and nearly 100 rolls per hour average for the ship.

### Hand Lift Trucks

While there have been no radical changes in the design of portable elevators or lift trucks during the past year, the use of these forms of handling equipment has been extended to the solution of a wide range of handling problems. A very large percentage of the stackers now being furnished by the manufacturers are of special design, to meet special problems. Another distinct trend is toward the telescopic-frame type of portable elevator, which is suitable for use under balconies and low ceilings, and which may without any changes in the machine be extended in height so that it reaches to the ceiling of higher rooms of the plant. Another aid to the lift-truck method of handling has been the recent improvements which have been made in skid construction. Until comparatively recently the skids were made locally. Now, however, the lift-truck manufacturers have developed more durable and serviceable skids with steel frames. Because of the large number of skids made this phase of the industry now receives the attention which it deserves.

### Skid Shipment of Materials

Skid shipment of materials on an increasing scale represents a trend in handling that cannot be ignored. Improved tying methods for securing skids loaded with various commodities promise still further development of this system in new fields. Originally put to work in the paper industry, at least one notable new effort that has been successful has been putting skids to work between plants supplying railroads with supplies and their central storehouses. In turn, when these supplies are sent to line stores, the skid load is transferred intact. Mention is made elsewhere of the use of 10-ton electric lift trucks at the plant of the Hudson Motor Car Co. There fullest possible advantage is being taken of the economies to be derived through wider use of skids for handling materials in transit.

### Gasoline Truck and Tractor Equipment

In the field of gasoline equipment, a new gas-electric unit, designed for use in the battery compartment of a standard electric truck chassis, is to be noted. Improved characteristics for the unit, which is direct-connected instead of chain-connected, are claimed. For certain types of very rugged service as in forge shops, it is reported that the use of power units of this kind is being discontinued.

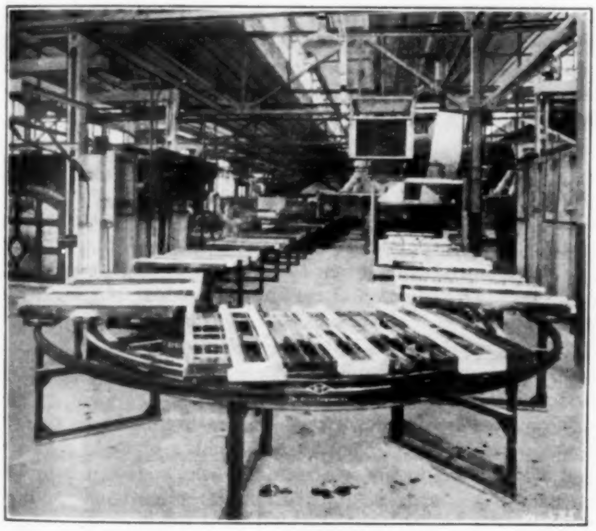
A new gasoline tractor of smaller dimensions for work in narrow aisles and for inside haulage, equipped with a so-called condensing silencer, has been introduced, which is said by its manufacturer to be capable of 24-hour service with remarkable economy.

### Conveyors

Idlers for belt conveyors have been improved, mainly through the perfection of bearings. Improved casings for elevating

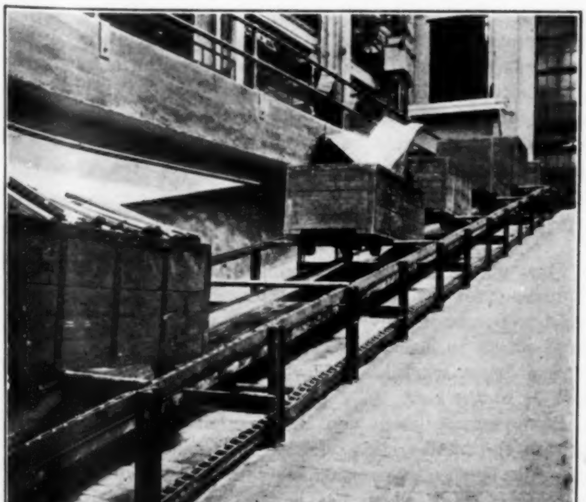
Loading Point for Tramrail System in Cotton Warehouse

Electric Truck Handling Skid Shipment

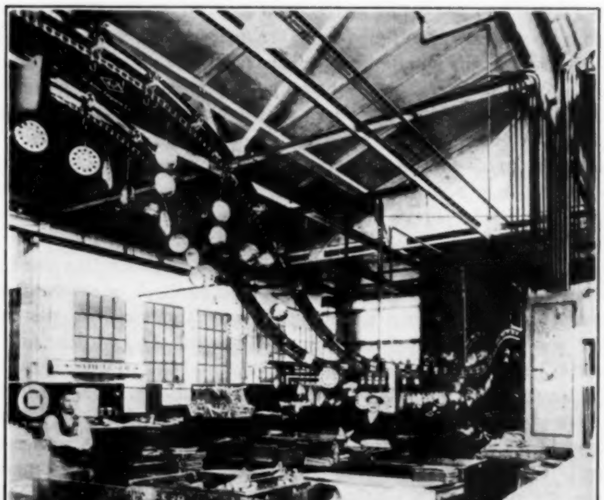


Carrousel Conveyor

Dust-Proof Gravity Roller Conveyor in Foundry



Chain Conveyor for Hand Trucks



Trolley Conveyor Using Link Chain

conveyors are noted. Chains and other conveyor parts to resist acid and alkaline atmospheres are in course of development. (This incidentally holds for the materials used in the construction of most types of materials-handling equipment.)

Particularly important developments have taken place during the year in the underground conveying of coal. Mechanical loaders for working at the room face are making it possible to maintain a given production with a much smaller number of rooms.

Use of single conveyor lines for carrying products of varying size is noted. Increased employment of overhead chain-type conveyors also is noted.

### Pneumatic Equipment

A type of pneumatic conveyor which has been built commercially somewhat less than a year has produced results which show important economies over other types of pneumatic or steam conveyors. As is the case with any new equipment, it was necessary to overcome difficulties, correct errors in construction, and make substitutions of materials and alterations for convenience of operation. A very recent test conducted in a plant having four 500-hp. boilers shows very satisfactory results.

The ashes at this plant are extremely variable in character due to the fact that wood refuse is burned under two of the boilers, while the other two are fired with a mixture of wood refuse and coal. In addition to the above, crating, boxes, etc. are broken up, and with the nails, form a rather heavy ash. Also there are a large number of sanding machines in the plant, and the fine wood refuse contains a considerable amount of sand which fuses with the ash in the furnace. This forms a hard, glass-like slag, which weighs about 135 to 140 lb. per cu. ft. Therefore the material to be handled ranges from light, fine, fluffy ashes to heavy slag weighing up to a maximum of 140 lb. per cu. ft. All of this material is handled through a duct having an internal diameter of 5.75 in. Tests conducted on this installation show an average capacity of about 13 to 15 tons per hour, with a steam consumption of about 240 lb. per ton of materials handled.

## INDUSTRY DEVELOPMENTS

### Layout Studied in Paper Industry

The layout of the modern pulp and paper mill has been getting a great deal of study by the industry in an endeavor to reduce to a minimum the labor in handling raw products. The entire plant has been so designed that the materials flow in a logical manner from the raw product to the finished commodity. This has involved considerable handling equipment, and perhaps the best example of the modern mill is the new Gatineau Plant of the Canadian International Paper Company. Provision has been made at this plant for adequate storage of pulpwood, sulphur, lime, and other materials, and the conveying systems from storage to the mill are well arranged and allow for future expansion.

Pulpwood handling has been given much consideration during the last year and a half, and several new methods of mechanical conveyance have been adopted. One of the most interesting is the new loading and unloading equipment used by the Anticosti Corporation for handling 4-ft. pulpwood to and from vessels. This equipment consists of a pulpwood grab or "trapper," which is lowered into a restricted basin filled with 4-ft. pulpwood. The load is transferred to the hold of the vessel, where it is tiered up. The unloading procedure is carried on in the reverse manner, by means of a platform which will hold about one cord, and this is lifted from the hold of the ship and dumped into a conveyor. This equipment makes it possible to load and unload pulpwood many times faster than by the old methods, and the cost of handling is substantially reduced.

Recently equipment has been developed to handle long logs by the use of a sling arrangement. This eliminates the necessity of cutting them into 4-ft. lengths, and speeds up the loading and unloading operations both from cars and vessels.

The use of air to handle granular material such as clay, sulphur, and lime has been adopted by a number of mills in the pulp and paper industry. The cost of handling is reduced, and, what is more important, the dust in handling is practically eliminated, thus giving the workmen a great deal more comfort in unloading such materials from cars.

Air conveying equipment for chips and semi-dry pulp has also been developed and adopted in some particular cases.

The electric lift truck is being more commonly adopted by the pulp and paper industry for a number of commodities such as lap pulp, pulpwood, paper, and similar materials that are piled on platforms. This method eliminates considerable handling, and in the case of finished paper reduces the damage of spoilage due to poor handling methods. The overhead crane has enabled many mills to solve the handling problems when such materials as baled paper, rags, and similar products are used. This equipment is also used by a number of the mills to handle finished and semi-finished paper, and although it is not essentially new, the mechanical principles involved are being used to a better advantage than several years ago.

### Foundry Practice Developing

A general trend toward mechanization, which started perhaps 15 years ago, has been accentuated by highly competitive conditions among foundries. Mechanical handling, covering sand, fuel, metal, and finished castings, has made tremendous advances. The adoption of continuous molding, melting, pouring, cooling, and shake-out has greatly decreased the cost and increased the production of the larger plants producing a standard line. The continuous pouring system does not apply, however, to small or jobbing foundries.

A radiator foundry reports 50 per cent saving in floor space, a reduction of 75 per cent in the number of flasks required, and that the production per man has been increased from 5.75 molds of one class to 9.70 of the same type per hour, and from 18.25 to 30.55 molds per man-hour on a smaller hob.

Every new foundry built and every shop which has revised its equipment has gone the limit on conveying and handling equipment during the past 18 months.

Improvement in quality of product and increased pressure on merchandising methods probably will have the major attention of foundry executives in the next few years. Cutting corners on production costs, and improvements in manufacturing methods along present known lines, probably have reached the high point, although many establishments still could apply these factors to existing practice.

### The Construction Field

Most of the motor-truck manufacturers are building special equipment for road-building operations. These include special-sized bodies, bodies divided into batch compartments, and wide-tired wheels to decrease the unit weight on the road subgrade. In one case a truck has been developed which dumps to either side or to the rear.

Power-shovel design and construction have recently turned toward the smaller sizes of shovels, $^1/_2$ and $^3/_4$ yd. capacity, resulting in speed, operating mobility, and adaption to a large volume of work which has heretofore been uneconomical for large-shovel operation. On gasoline shovels, air-operated

clutches are contributing to flexibility of operation. Somewhat along the same line air engines are being used direct-connected to the crowding and swinging motions of one shovel.

On all construction equipment steel castings have been replacing cast iron and riveted structural steel. In the past year extremely large unit steel castings have been used on some equipment. In one case a power shovel uses a single steel casting for the entire body frame and the bearing supports for all of the main bearings.

Roller and ball bearings are becoming standard equipment. At the 1927 road show of the American Road Builders Association, fully 50 per cent of the machines exhibited were equipped with such bearings. Of the other bearings used on construction machines, most of them are bronze-bushed, and practically all are of the split type to facilitate easy adjustment.

Much activity has been evident in lubrication development. Pressure systems of the Alemite and the Dot type are becoming commonplace. A more recent development is the use of totally enclosed gears running in oil.

A hoist manufacturer has developed a three-speed hoist using a motor-truck-type transmission. Portable conveyors, both of the belt and bucket type, and belt-conveyor installations for handling stone, cement, and other construction material, are continually being adapted to new construction uses.

### The Railway Field

The applications of materials-handling machinery and devices in the railroad field are so diversified and extensive that it is held by one close to the situation almost impossible to give any summary as to the progress which has been made with any degree of accuracy. It is known that in each department there has been a steady increase in materials-handling devices and equipment in the interest of increased efficiency and greater economy of operation. As far as is known, there have been no startling improvements adopted on an extensive scale in any of the departments. The progress has been more in the extended and greater use of equipment and methods which were adopted by the more progressive roads in recent years.

In connection with materials handling in the railroad field, reference may be made to the fairly recent utterance of an authority close to present methods of freight handling. He pointed out that long-haul profits are being needlessly sacrificed in the terminal handling of freight, estimating that a saving of $25,000-000 is possible through the fully effective use of mechanical freight-handling facilities already at the disposal of railroads.

Skid shipment, already alluded to, represents an important development certain to be more widely practiced in the future.

Another change in railroad practice that already has come in some sections of the country, is store-door delivery. This will involve a tremendous expenditure in new short-haul materials transportation, and because of the experience of the American Express Co., which is the largest user of electric street trucks in the world, it is believed that this may become a recognized type of equipment in this branch of railway service.

### Marine Handling

The most significant development in marine terminals during the past year, at least on the Pacific Coast, has been the remarkable increase in the percentage of shipments handled to and from such terminals by trucks and the decreasing percentage handled by rail. As shown by a paper read before the Pacific Coast Association of Port Authorities by Harbor Engineer Nicholson of Los Angeles, the future piers of Los Angeles Harbor will have to be designed to accommodate 60 per cent or more of the traffic being handled by trucks. The same ratio of truck traffic is being approached in San Francisco, Seattle, and Portland. If this increase continues it may mean the redesigning and rebuilding of every pier on the Pacific Coast, and will certainly mean the introduction into pier sheds of a far more comprehensive system of mechanical handling than at present prevails.

At least one new experimental machinery installation has been made on the Pacific Coast which may lead to a large introduction of such machinery. On the passenger and freight steamer *City of Honolulu* there has been introduced a conveyor system for handling general freight from side ports through hatches of the lower decks and into the hold spaces. Initial trips of this vessel indicate that this method of handling freight on combination passenger and freight steamers will be highly successful. Tests during the first trip indicated an overall saving of some 30 per cent as compared with ship's winches and tackle in the handling of pineapples in cases.

It is altogether likely that the development trend in materials-handling machinery at marine terminals for Pacific Coast use will have to be directed toward a condition catering to truck transport.

### The Ceramic Industries

For several years the common brick plants have experimented with cranes whereby they could progress the brick through drying and firing in units of from 2 to 500. This has involved the devising of kilns with removable crowns. In this system the bricks are kept in blocks of 2 to 500 throughout the process, even to the loading on to the cars or barges. The extension of this principle to brick manufacturing in general would result in great improvements and economies.

The most important development in pottery plants has been the tunnel kiln, in which the pottery products are fired while in constant motion through a long tunnel, the heat being applied at the middle of the kiln.

Other developments in materials handling have affected this industry chiefly from the standpoint of transporting the raw materials and unfinished and finished products by means of belt conveyors. Driers with automatic heat and humidity control and suitable conveying systems have come into use quite extensively.

The principal development of the future will be in the still greater application of continuous firing systems and continuous movement of the ware through the several processes, in the opinion of an authority close to the industry.

Summarizing, developments of note include:

Tendency to better organization within the plant for the control of materials-handling equipment

Tendency to handle heavier loads fewer times

Tendency to move material direct from freight cars to production machines instead of into raw-materials stores

Tendency to reduce the amount of work in process and the storage reservoirs of partly or wholly finished parts

Tendency to tie the materials-handling system directly into that used for production

Tendency to modernize facilities for handling in smaller plants, and in plants where comparatively low tonnages have to be transported.

Conveyor for Coal and Ash Handling in Boiler Plants (Der gegenwärtige Stand des Transportwesens zur Bekohlung und Entaschung von Dampfkesseln), F. Riedig. Fördertechnik u. Frachtverkehr, vol. 19, nos 11 and 12, May 28 and June 11, 1926, pp. 157–160 and 176–180, 25 figs.

Pneumatic Coal Conveying at Bestwood Colliery, near Nottingham. Iron & Coal Trades Rev., vol. 114, no. 3079, Mar. 4, 1927, pp. 347–349, 10 figs.

**Developments.** A Brief Review of Some Recent Developments in Coal and Coke Handling and Storage, H. Blyth. Gas Engr., vol. 43, no. 609, Jan. 1927, pp. 5–7, 4 figs.

**Equipment.** Economic Fuel Handling and Storage, W. T. Conlon. Mfg. Industries, vol. 12, no. 2, Aug. 1926, pp. 97–100, 5 figs.

Modern Coal-Handling Equipment, E. Zeuthen. Elec. World, vol. 87, no. 2, Jan. 9, 1926, pp. 87–89, 3 figs.

Solving the Coal and Ash Handling Problem, E. J. Tournier. Indus. Mgmt. (N. Y.), vol. 72, no. 2, Aug. 1926, pp. 77–87, 27 figs.

The Mechanical Handling of Coal, G. E. Titcomb. Black Diamond, vol. 76, no. 6, Feb. 6, 1926, pp. 140–141 and 147, 6 figs.

**Flume, Transportation by.** Long Flume Transports Coal in Hilly Region, G. Townsend. Coal Age, vol. 29, no. 5, Feb. 4, 1926, pp. 185–187, 4 figs.

**Gas Works.** Coal Handling Plants of the Gas Light and Coke Company, G. F. Zimmer. Indus. Mgmt. (Lond.), vol. 13, no. 9, Sept. 1926, pp. 383–387 and 391, 3 figs.

Gas Works Coal-Handling Plant. Engineering, vol. 122, no. 3180, Dec. 24, 1926, pp. 779–781, 13 figs. partly on p. 788.

New Fuel Handling Equipment at Atlantic City, C. W. Ross. Gas Age-Rec., vol. 58, no. 21, Nov. 20, 1926, pp. 725–726, 4 figs.

**Hydraulic Hoists.** New Coal Hoists in South Wales. Engineer, vol. 144, no. 3735, Aug. 12, 1927, pp. 184–185.

New Hydraulic Electric Coal Hoists at Cardiff. Engineer, vol. 142, no. 3691, Oct. 8, 1926, pp. 385–388, 7 figs.

**Hydraulic Unloading.** Hydraulic Unloading of Coal Trucks for Power Houses, P. Calfas. Indus. Mgmt. (Lond.), vol. 13, no. 10, Oct. 1926, pp. 424–425, 3 figs.

**Industrial Plants.** The Coal Handling and Storage Equipment of the Dye Works of Meister, Lucius and Bruning, at Höchst-on-the-Main (Die Kohlen-Förder- und Lageranlagen der Farbwerke vorm. Meister, Lucius & Bruning in Höchst a.M.), Buhle. Bautechnik, vol. 5, nos. 1 and 7, Jan. 1 and Feb. 11, 1927, pp. 7–9 and 87–90, 29 figs.

**Interlocking Bridges.** Flexible Handling of Coal in Quantity. Iron Age, vol. 120, no. 1, July 7, 1927, pp. 14–15.

**Loaders.** The Sullivan Coal Loader. Colliery Guardian, vol. 132, no. 3429, Sept. 17, 1926, p. 618, 1 fig.

**Loading Bridge.** Coal-Loading Bridge with Screening Equipment (Kohlenverladebrucke mit Sieberei). V.D.I. Zeit., vol. 71, no. 26, June 25, 1927, pp. 929–930, 3 figs.

**Loading Plant.** Great Western Railway Coal Loading Plant at Port Talbot. Engineering, vol. 122, no. 3160, Aug. 6, 1926, pp. 162–164, 22 figs.

**Locomotive Loading Equipment.** Locomotive Coaling (De kolenvoorziening van locomotieven), J. P. Boezaardt. Ingenieur, vol. 42, no. 12, Mar. 19, 1927, pp. 213–226, 28 figs.

**Machinery.** Coal-Handling Machinery at Hull. Shipbldg. & Shipg. Rec., vol. 27, no. 23, June 10, 1926, pp. 612–614, 4 figs.

**Methods.** Modern Methods in Coal and Ash Handling, W. W. Sayers. Power, vol. 64, nos. 4, 5, 6, 7 and 8, July 27, Aug. 3, 10, 17 and 24, 1926, pp. 133–136, 169–171, 204–206, 240–241 and 284–286, 35 figs.

**Paper Mills.** Coal Handling and Boiler Operation at Northern Paper Mills, H. W. Gochnauer. Mfg. Industries (Mgmt. & Admin.), vol. 11, no. 1, Jan. 1926, pp. 23–24, 5 figs.

**Plants.** Coal Handling Plant at Liverpool Corporation Electricity Works. Eng. & Boiler House Rev., vol. 40, no. 4, Oct. 1926, pp. 184–186, 1 fig.

Coal-Handling Plant at the Gas Light and Coke Company's Beckton Works. Engineering, vol. 122, nos. 3174 and 3176, Nov. 12 and 26, 1926, pp. 589–591 and 650–653, 39 figs. partly on supp. plates.

Conveying Plants for Coal (Förderanlagen für Kohle), K. Wagner. Elektro Jl., vol. 5, no. 24, Dec. 25, 1926, pp. 435–442, 18 figs.

New Coal Handling Plant at Beckton. Engineer, vol. 142, no. 3679, July 16, 1926, pp. 61–71, 4 figs.

**Pneumatic.** Pneumatic Handling of Coal, Flue Dust and Ashes. Eng. & Boiler House Rev., vol. 40, no. 9, Mar. 1927, pp. 464–471, 4 figs.

Pneumatic Conveying of Coal. Colliery Guardian, vol. 133, no. 3453, Mar. 4, 1927, pp. 501–502, 8 figs.

**Pneumatic Plants.** Handling Coal Pneumatically at the Sittingbourne Works of Edward Lloyd, Limited. Iron & Coal Trades Rev., vol. 114, no. 3076, Feb. 11, 1927, pp. 215–217, 6 figs.

Pneumatic Coal and Ash Conveying Plant. Engineer, vol. 143, no. 3709, Feb. 11, 1927, pp. 163–166, 9 figs. partly on p. 160.

Pneumatic Coal-Conveying Plant. Colliery Eng., vol. 3, no. 30, Aug. 1926, pp. 356–359 and 370, 10 figs.

Pneumatic Coal Handling Plant in a London Brewery, J. S. Gander. Eng. & Boiler House Rev., vol. 40, no. 8, Feb. 1927, pp. 399–404, 5 figs.

**Power Plants.** Handling of Fuel and Waste in Electric Generating Stations, A. Barnes. Indus. Mgmt. (Lond.), vol. 13, no. 3, Mar. 1926, pp. 139–144, 7 figs.

Methods of Handling Fuel and Waste in the Power House, G. F. Zimmer. Indus. Mgmt. (Lond.) (Cassier's Works Power No.) vol. 13, no. 2. Feb. 1926, pp. 96-102, 6 figs.

Modern Coal and Ash Handling Plant. Eng. & Boiler House Rev., vol. 40, no. 1, July 1926, pp. 3-16, 7 figs.

Modern Fuel Handling in Power Plants. Power Plant Eng., vol. 30, no. 10, May 15, 1926, pp. 589-594, 13 figs.

**Shipment.** Recent Developments in the Shipment of Coal at South Wales Ports, J. Auld. Inst. Transport—Jl., vol. 7, no. 4, Feb. 1926, pp. 162-172 and (discussion) 172-182, 7 figs.

Speed and Economy in the Shipment of Export Coal, G. Bulkeley. Colliery Eng., vol. 3, nos. 23, 24, 25 and 26, Jan., Feb., Mar., and Apr. 1926, pp. 7-8, 70-72 and 128-130, 15 figs.

**Shipping Plants.** Modern Coaling Plants for Ships, J. Kahrmann. Eng. Progress, vol. 7, no. 9, Sept. 1926, pp. 229-233, 10 figs.

**Ships.** Modern Ship-Coaling Plants (Neuzeitliche Schiffsbekohlungsanlage), J. Kahrmann. Zeit. des Vereines deutscher Ingenieure, vol. 70, no. 34, Aug. 21, 1926, pp. 1117-1121, 11 figs.

**System.** The Installation of a Coal Handling, Screening and Storing System at the Nassau Works of the Brooklyn Union Gas Co., L. S. Stiles. Bklyn. Engrs.' Club—Proc., vol. 24, part 2, Jan. 1926, pp. 31-52, 19 figs.

**Towers.** A Four-Ton Coal-Handling Tower, M. R. Summer. Elec. World, vol. 88, no. 13, Sept. 25, 1926, pp. 653-654, 6 figs.

Coal Towers of Reinforced Concrete (Kohlentürme aus Eisenbeton), H. Butzer. Bauingenieur, vol. 7, no. 10, Mar. 5, 1926, pp. 195-204, 15 figs.

**Transportation.** Coal Transport in France, Belgium and Germany, C. E. R. Sherrington. Ry. Gaz., vol. 44, no. 16, Apr. 16, 1926, pp. 549-553.

**Unloaders.** Hydraulic Unloading of Coal (Le déchargement hydraulique du charbon), P. Calfas. Génie Civil, vol. 88, no. 13, Mar. 27, 1926, pp. 289-292, 6 figs.

2,000 Ton Coal Handling Plant and Automatic Weighing Machines. Eng. & Boiler House Rev., vol. 40, no. 3, Sept. 1926, pp. 128-132, 2 figs.

Unloading Devices for Mineral Trucks, W. A. Harris. Indus. Mgmt. (Lond.), vol. 13, nos. 6 and 8, June and Aug. 1926, pp. 233-238 and 353-354, 366 and 368, 18 figs.

**Wharf Facilities.** B. & M. Erects Large Coal Handling Facilities at Boston. Ry. Age, vol. 82, no. 15, Mar. 12, 1927, pp. 885-888, 4 figs.

**COAL MINES**

**Conveyor Loaders.** Face Conveyor-Loader at Cannock Chase Collieries. Iron & Coal Trades Rev., vol. 114, no. 3086, Apr. 22, 1927, p. 638.

**Conveyors.** An Improved Face Conveyor, A. V. Reis. Iron & Coal Trades Rev., vol. 114, no. 3094, June 17, 1927, p. 965, 1 fig.

Conveyors Applied to Room and Pillar Mining, F. H. Coleman. Min. Congress Jl., vol. 13, no. 6, June 1927, pp. 453-454.

Conveyor as Applied to Long Wall Mining, D. A. Thomas. Min. Congress Jl., vol. 13, no. 6, June 1927, pp. 451-452.

Conveyors Work Well in Thin-Seam Mines, J. J. Rutledge. Coal Age, vol. 29, no. 6, Feb. 11, 1926, pp. 225-229, 9 figs.

Developments in Electrically Driven Jig Conveyors (Die Aussichten für die Weiterentwicklung der elektrisch betriebenen Schüttelrutsche), Wintermyer. Bergbau, vol. 39, no. 37, Sept. 16, 1926, pp. 516-518, 3 figs.

Flexible System of Belt Conveyors Is Applied to Thin-Seam Room-and-Pillar Mining, J. H. Edwards. Coal Age, vol. 29, no. 7, Feb. 18, 1926, pp. 255-258, 6 figs.

Installation of Underground Conveyors, J. G. Scoular. Colliery Guardian, vol. 83, no. 3465, May 27, 1927, pp. 1233-1234.

Installation Provides Data on Lessened Breakage Incurred with Rope-and-Button Conveyor. Coal Age, vol. 31, no. 18, May 5, 1927, pp. 629-630, 5 figs.

Operation of Retarding Conveyors and Hoists Calls for Understanding of Regenerative Braking. Coal Age, vol. 31, no. 19, May 12, 1927, pp. 682-684, 3 figs.

Shaking Conveyors on Pillar Recovery, G. F. Osler. Min. Congress Jl., vol. 13, no. 6, June 1927, p. 473.

The Economic Advantages of Bucket Conveyors to German Mining (Welche wirtschaftlichen Vorteile bietet die Kübelförderung dem deutschen Bergbau?), P. Walter. Braunkohle, vol. 25, no. 45, Feb. 5, 1927, pp. 997-1007, 15 figs.

Year Gives Great Impetus to Use of Conveyors Underground in Many Coal Fields, A. F. Brosky. Coal Age, vol. 29, no. 3, Jan. 21, 1926, pp. 70-76, 12 figs.

**COAL MINING**

**Conveyor Loading.** Conveyor Loading for Entries, B. L. Lubelsky. Modern Min., vol. 4, no. 5, May 1927, pp. 138-141, 4 figs.

Coal-Conveying, as Applied to the Barnsley Bed of South Yorkshire, B. H. Pickering. Instn. of Min. Engrs.—Trans., vol. 71, May 1926, pp. 370-375 and (discussion) 375-380, 3 figs.

Face Conveyors with Concentrated Mining System, F. S. Follansbee. Min. Congress Jl., vol. 12, no. 4, Apr. 1926, pp. 279-281 and 293-296, 2 figs.

Installing and Moving Room Conveyors, N. D. Levin. Min. Congress Jl., vol. 12, no. 4, Apr. 1926, pp. 283 and 297-298, 5 figs.

Mine in Scotts Run District Removes Pittsburgh Coal by Aid of Conveyors, A. F. Brosky. Coal Age, vol. 29, no. 20, May 20, 1926, pp. 701-705, 10 figs.

Using Shaking Conveyor in Lignite Mines Underground (Die Anwendung von Schüttelrutschen im Braunkohlentiefbau), W. Elbert. Braunkohle, vol. 25, no. 15, July 10, 1926, pp. 309-315, 5 figs.

**COKE HANDLING**

**Methods and Equipment.** The Special Problems Involved in the Handling of Industrial Coke, E. J. Tournier. Indus. Mgmt. (N. Y.), vol. 72, no. 3, Sept. 1926, pp. 189-196, 15 figs.

**CONVEYORS**

**Aerial Ropeways.** Transportation by Aerial Ropeways. So. African Min. & Eng. Jl., vol. 38, no. 1866, July 2, 1927, pp. 519-520.

**Ash.** A New Ash Conveyor, C. W. Edwards. Combustion, vol. 15, no. 1, July 1926, pp. 35-37, 3 figs.

**Automobile Industry.** Conveyors Use in the Automotive Industry, C. A. Brock. Soc. Automotive Engrs.—Jl., vol. 19, no. 4, Oct. 1926, pp. 343-350, 18 figs.

Transportation by Conveyor, P. Phelps and N. H. Preble. Soc. Automotive Engrs.—Jl., vol. 19, no. 4, Oct. 1926, pp. 413-421, 21 figs.

Transportation by Conveyor. Soc. Automotive Engrs.—Jl., vol. 20, no. 4, Apr. 1927, pp. 519-520.

**Ball-Frame.** Eickhoff Ball-Frame Conveyor. Iron & Coal Trades Rev., vol. 112, no. 3024, Feb. 12, 1926, p. 301, 8 figs.

**Bearings and Lubrication.** Cutting Down Power Costs on Mechanical Handling Equipment, A. F. Brewer. Indus. Mgmt. (N. Y.), vol. 74, no. 2, Aug. 1927, pp. 101-105, 9 figs.

**Belt.** Belt Conveyor at Lignite Mine of Gewerkschaft Grosskraftwerk Main-Weser, Germany (Die Gurtbandförderanlage der Gewerkschaft Grosskraftwerk Main-Weser bei Borken (Bez. Kassel)), W. Regling. Braunkohle, vol. 25, no. 39, Dec. 25, 1926, pp. 885-889, 5 figs.

Belt Conveyors and Elevators in Rock Products Plant, T. U. Hawkins. Belting, vol. 30, no. 4, Apr. 1927, pp. 15-18, 7 figs.

Belt Conveyors in Cold Storage Refrigerating Plant, W. A. Scott. Belting, vol. 28, no. 4, Apr. 1926, pp. 20-22, 4 figs.

Extensive Belt Conveyor System for Iron Ore Concentration Plant. Indus. Mgmt. (Lond.), vol. 13, nos. 9 and 10, Sept. and Oct. 1926, pp. 392 and 434, 3 figs.

Material Handling with Belt Conveyors. Buildings, vol. 65, no. 6, June 23, 1926, pp. 261-263, 6 figs.

New Belt Conveyor at Bargoed Colliery. Iron & Coal Trades Rev., vol. 114, no. 3072, Jan. 14, 1927, pp. 39-40, 6 figs.

Rubber Belt Conveyers and Chute Linings in Gravel Plants, R. A. Goodwin. Belting, vol. 28, no. 3, Mar. 1926, pp. 19-20, 22 and 24, 10 figs.

Selection, Installation and Care of Belt Conveyors, W. E. Phillips. Cement Mill & Quarry, vol. 30, no. 5, Mar. 5, 1927, pp. 19-25, 2 figs.

The Belt Conveyor and Its Advantages. Indus. Mgmt. (Lond.), vol. 14, no. 2, Feb. 1927, pp. 47-48.

Unusual Conveyor Problem at Cincinnati Plant, R. A. Goodwin. Cement Mill & Quarry, vol. 30, no. 3, Feb. 5, 1927, pp. 18-20, 5 figs.

**Bottles and Crockery.** Handling Bottles and Crockery Mechanically, G. F. Zimmer. Indus. Mgmt. (Lond.), vol. 13, no. 11, Nov. 1926, pp. 451-453, 4 figs.

**Chain.** Researches on Conveyor Chains for Open-Cut Lignite Workings (Untersuchungen an Förderketten für Braunkohlentagebaue), A. Pomp. Braunkohle, vol. 25, no. 47, Feb. 19, 1927, pp. 1037-1047, 17 figs.

**Coal.** New Coal Face Conveyor, A. V. Reis. Indus. Mgmt. (Lond.), vol. 14, no. 8, Aug. 1927, pp. 286-287, 1 fig.

**Cooling Confectionery on.** Cooling Confectionery on a Conveyor. Indus. Mgmt. (Lond.), vol. 14, no. 4, Apr. 1927, pp. 127-128, 2 figs.

**Cotton Mills.** Planning a Cotton Mill Around the Conveyor System, C. M. Mumford and M. G. Farrell. Indus. Mgmt. (N. Y.), vol. 74, no. 2, Aug. 1927, pp. 94-100, 15 figs.

**Dual.** Dual or Multi-Purpose Conveyors, G. F. Zimmer. Indus. Mgmt. (Lond.), vol. 14, no. 2, Feb. 1927, pp. 41-46 and 50, 7 figs.

**Electric Drive.** Application of Electric Drive to Conveyors, R. F. Emerson. Eng. World, vol. 30, no. 3, Mar. 1927, pp. 143-150, 14 figs.

The Application of Electric Drive to Conveyors, R. F. Emerson. Gen. Elec. Rev., vol. 30, no. 2, Feb. 1927, pp. 93-101, 14 figs.

**Factory.** Controlling Production Mechanically, Wm. F. Bailey. Factory, vol. 36, no. 2, Feb. 1926, pp. 262-265, 340, 342, 344, 346, 348 and 350, 14 figs.

Conveyor Slash Handling Costs, G. Prifold. Factory, vol. 37, no. 4, Oct. 1926, pp. 618-620, 5 figs.

**Foundries.** Savings from the Use of Conveyors in Manufacturing. Iron Age, vol. 120, no. 1, July 7, 1927, pp. 1-5, 8 figs.

**Industrial Applications.** The Industrial Application of Conveyor Systems, C. A. Burton. Mech. Eng., vol. 49, no. 4, Apr. 1927, pp. 355-356.

**Jig.** Investigations of the Motion of Jig Conveyors (Untersuchungen über die Bewegungsvorgänge bei der Schüttelrutschenförderung), W. Stuhlmann. Glückauf, vol. 62, no. 12, Mar. 20, 1926, pp. 363-368, 8 figs.

**Laundries.** Conveying Methods in Modern Laundries, G. F. Zimmer. Indus. Mgmt. (Lond.), vol. 13, no. 8, Aug. 1926, pp. 345-347 and 353, 4 figs.

**Lubrication.** Modern Methods in Lubrication and Transmission, F. A. Robinson. Belting Transmission Tools & Supplies, vol. 31, no. 1, July 1927, pp. 16-21, 6 figs.

Problems in Lubricating Conveyors, F. E. Gooding. Indus. Engr., vol. 84, no. 11, Nov. 1926, pp. 513-517, 10 figs.

**Machine-Hour Rate System.** New Cost Basis for Material Handling, F. E. Moore. Mfg. Industries, vol. 11, no. 3, Mar. 1926, pp. 169-170, 4 figs.

**Machine Shops.** How Conveyors Saved Erecting New Buildings, F. H. Colvin. Am. Mach., vol. 65, no. 11, Sept. 9, 1926, pp. 437-439, 7 figs.

**Mechanical Control.** It's Almost Human, A. J. Howe. Factory, vol. 37, no. 6, Dec. 1926, pp. 998-1001, 1020 and 1024, 10 figs.

**Monorail Runways.** Arch Beam Monorail Runway. Iron Age, vol. 118, no. 15, Oct. 7, 1926, p. 1003, 3 figs.

**Motor Control.** "Telephone-Exchange" Control for Conveyor System, R. G. Lockett. Elec. World, vol. 89, no. 12, Mar. 19, 1927, pp. 603-604, 2 figs.

**Natural-Frequency.** Natural Frequency Conveyors. Machy. (Lond.), vol. 28, no. 723, Aug. 19, 1926, pp. 573-575, 7 figs.

**Newspaper.** Newspaper Conveyors, G. F. Zimmer, Indus. Mgmt. (Lond.), vol. 13, no. 12, Dec. 1926, pp. 487-490, 4 figs.

Newspaper Conveyors. Indus. Mgmt. (Lond.), vol. 14, no. 8, Aug. 1927, pp. 277-279, 3 figs.

**Overmotoring.** Preventing Overmotoring of Conveyors, R. F. Emerson. Power, vol. 63, no. 19, May 11, 1926, pp. 703-704, 1 fig.

**Pneumatic.** Pneumatic Coal Conveying Plant at the Sittingbourne Paper Mills. Indus. Mgmt. (Lond.), vol. 14, no. 8, Aug. 1927, pp. 283-285, 6 figs.

Pneumatic Conveying of Gritty Materials, E. J. Tournier. Rock Products, vol. 30, no. 2, Jan. 22, 1927, pp. 40-50, 12 figs.

Pneumatic Conveying Plants for Agricultural Purposes, L. Engelbrecht. Eng. Progress, vol. 7, no. 12, Dec. 1926, pp. 327-328, 3 figs.

The "Pneuconex" Pneumatic Conveyor System. Machy. Market, no. 1388, June 10, 1927, pp. 21-23, 4 figs.

The "Pneuconex" System of Pneumatic Conveyance. Iron & Coal Trades Rev., vol. 114, no. 3091, May 27, 1927, pp. 847-848, 2 figs.

**Progressive Production.** Handling Devices and Progressive Manufacturing Processes, Wolther. Indus. Mgmt. (Lond.), vol. 14, no. 6, June 1927, pp. 197–201, 10 figs.

**Reciprocating.** New Type of Reciprocating Conveyor. Indus. Mgmt. (Lond.), vol. 14, no. 4, Apr. 1927, p. 126.

**Screw.** The Screw Conveyor and Its Manufacture, D. C. Wright. Am. Mach., vol. 64, nos. 24 and 25, June 17 and 24, 1926, pp. 931–933 and 977–980, vol. 65, no. 1, July 1, 1926, 19 figs.

**Shaking.** Movements in Conveying Troughs with Rotary Drive (Ueber die Bewegungsvorgänge bei Förderrinnen mit umlaufenden Antrieben), W. Stuhlmann. Bohrhammer, vol. 6, no. 51, Jan. 1926, pp. 5–10, 8 figs.

Movements of Shaking Conveyors with Special Reference to Pneumatic Drive (Ueber die Bewegungscoränge bei der Schüttelrutschenförderung mit besonderer Berücksichtigigung der Pressluftantriebe), W. Stuhlmann. Fördertechnik u. Frachtverkehr, vol. 19, nos. 14, 15, 16 and 17, July 9, 23, Aug. 6 and 20, 1926, pp. 205–208, 228–231, 243–245 and 260–264, 14 figs.

Prospects for Further Development of Electrically Driven Shaking Conveyors (Die Aussichten für die Weiterentwicklung der elektrische betriebenen Schüttelrutsche), M. Wintermeyer. Bergbau, vol. 39, no. 37, Sept. 16, 1926, pp. 516–518, 3 figs.

Transport by Shaking Conveyors (Le transport en taille par couloirs oscillants), F. Quievreux. Société Industrielle de Mulhouse—Bul., vol. 42, no. 6, June-Aug. 1926, pp. 331–348, 8 figs.

**Telegraph Stations, United States.** Mechanical Conveying in Large Telegraph Centers of United States (Les transporteurs mécaniques dans les grands centraux télégraphiques des Etats-Unis), J. Jacob. Technique Moderne, vol. 18, no. 4, Feb. 15, 1926, pp. 97–102, 14 figs.

**Theory of.** Position of Driving Gear and Magnitude of Stress in the Pulling Member of an Endless Conveyor (Die Lage des Antriebes und die Zugorganspannkraft von Förderern mit endlosem Zugorgan), Heumann. Fördertechnik u. Frachtverkehr, vol. 19, nos. 4 and 5, Feb. 18 and Mar. 4, 1927, pp. 85–89 and 101–105, 13 figs.

**Tramrail System.** Special Carrying Rail, A. F. Anjesky. Iron Age, vol. 117, no. 23, June 10, 1926, p. 1651, 1 fig.

**Types.** Mechanical and Continuous Handling of Diversified Products, E. J. Tournier. Indus. Mgmt. (N. Y.), vol. 73, no. 6, June 1927, pp. 328–333, 6 figs.

**Vibration-Type.** Vibration-Type Conveyor (Der Wuchförderer ein neues Fördermittel), H. Heymann. Zeit. des Vereines deutscher Ingenieure, vol. 70, no. 10, Mar. 6, 1926, pp. 309–313, 13 figs.

**Wood Shavings.** Design of Conveyors for Wood Shavings (Die Berechnung der Spänetransport-Anlagen), S. Grakhan. Fördertechnik u. Frachtverkehr, vol. 19, no. 4, Feb. 18, 1927, pp. 92–95.

**CRANES**

**A.C. and D.C. Motors for.** A.C. and D.C. Motors for Crane Operation, R. F. Emerson. Indus. Engr., vol. 85, no. 7, July 1927, pp. 315–316, 2 figs.

**Accidents.** Mechanical Causes of Crane Accidents, M. C. Goodspeed. Safety Eng., vol. 53, no. 6, June 1927, pp. 253–255.

**Austrian Types.** Modern Hoisting Equipment (Neuere Hebezeuge), R. Dub. Fördertechnik u. Frachtverkehr, vol. 19, nos. 24, 25 and 26, Nov. 26, Dec. 10 and 24, 1926, pp. 367–372, 387–390 and 403–407, 15 figs.

**Automobile.** Automobile Cranes (Automobilkrane), F. Woeste. Fördertechnik u. Frachtverkehr, vol. 20, no. 6, Mar. 18, 1927, pp. 117–121, 8 figs.

**Bridge, Brakes for.** Automatic Protective Brake for Traveling Loading Bridges and Cranes (Selbsttätige Windschutzbremse für fahrbare Verladebrücken und Krane), Uebbing. Fördetechnik u. Frachtverkehr, vol. 19, no. 5, Mar. 5, 1926, pp. 61–62, 2 figs.

**Building.** Building Cranes (Ueber Baukrane), W. Lattmann. Schweizerische Bauzeitung, vol. 87, no. 1, Jan. 2, 1926, pp. 8–10, 5 figs.

**Cable.** The Varied Use of Cable Cranes (Die vielseitige Verwendung von Kabelkranen), H. Schulze-Manitius. Fördertechnik u. Frachtverkehr, vol. 19, nos. 15 and 16, July 23 and Aug. 16, 1926, pp. 225–228 and 239–243, 28 figs.

**Construction and Maintenance.** Aspects in Construction and Maintenance of Crane Installations (Gesichtspunkte für Bau und Instandhaltung von Krananlagen), F. Töpfl. Stahl u. Eisen, vol. 46, no. 18, May 6, 1926, pp. 601–609, 20 figs.

**Design.** Tendencies of Modern Crane Design, E. G. Diegehen. Mech. World, vol. 80, nos. 2063 and 2065, July 16 and 30, 1926, pp. 47–48 and 85–86.

**Drum Controllers.** Drum Controllers for Electric Overhead Traveling Cranes, J. F. Foley. Australasian Elec. Times, vol. 6, no. 6, June 28, 1927, pp. 413–414, 2 figs.

**Electric.** All-Welded Electric Crane Embodies New Features of Design. Iron Trade Rev., vol. 81, no. 6, Aug. 11, 1927, pp. 316–318, 5 figs.

Cranes for Use in Ports and Harbours. So. African Eng., vol. 38, no. 7, July 1927, pp. 140–142, 2 figs.

**Electric Derrick.** Electric Derrick Crane. Engineering, vol. 121, no. 3136, Feb. 5, 1926, pp. 108–109, 6 figs.

**Electric Motors for.** Power Consumption and Power Factor of Deri Motor in Driving Cranes Connected with an A.C. System (Energiesverbrauch und Leistungsfaktor des Derimotors im Kranbetrieb im Anschluss an Drehstromnetze), F. Jungblut. Fördertechnik u. Frachtverkehr, vol. 19, no. 9, Apr. 30, 1926, pp. 125–129, 7 figs.

Requirement of Deri Motors in Crane Operation (Energieverbrauch des Deri-Motors im Kranbetrieb), F. Jungblut. Fördertechnik u. Frachtverkehr, vol. 19, no. 25, Dec. 10, 1927, pp. 381–384.

**Electric, Operation.** Rules for the Safe Operation of Electric Overhead Traveling Cranes. Iron & Steel Engr., vol. 4, no. 1, Jan. 1927, pp. 25–26.

**Electric Traveling.** How Electric Traveling Crane Came. Iron Age, vol. 118, no. 9, Aug. 26, 1926, pp. 541–543.

**Electric Trolley Crabs.** The Structural Design of Electric Traveller Crabs, E. G. Fiegehen. Engineer, vol. 142, no. 3683, Aug. 13, 1926, pp. 178–179, 7 figs.

**Floating.** A 65-Ton Floating Crane (65t-Schwimmkran), Momber. Schiffbau, vol. 27, no. 4, Feb. 24, 1926, pp. 91–94, 5 figs.

A 200-Ton Floating Crane. Engineer, vol. 142, no. 3588, Sept. 17, 1926, p. 315, 2 figs. partly on p. 308.

Floating Crane of 300 Tons for Handling Concrete Blocks in Harbor of Valencia (Spain) [Grue flottante de 300 tonnes pour la manutention des blocs de béton dans le port de Valence (Espagne)]. Génie Civil, vol. 88, no. 4, Jan. 23, 1926, pp. 77–80, 10 figs.

Floating Crane of 300 Tons Lifting Capacity. Shipbldg. & Shipg. Rec., vol. 27, no. 3, Jan. 21, 1926, pp. 70–71, 4 figs.

Floating Cranes and Their Scope, G. F. Zimmer. Indus. Mgmt. (Lond.), vol. 14, no. 4, Apr. 1927, pp. 117–119, 5 figs.

**Full-Arch.** Cranes Increase Pier Capacity Over 300 Per Cent. Eng. News-Rec., vol. 96, no. 3, Jan. 21, 1926, pp. 118–119, 2 figs.

**Gantry.** Electric Traveling Gantry Crane of 480 Tons of Naval Artillery Ordnance at Gavre, France (Grue roulante électrique à portique, de 480 tonnes, du polygone de l'Artillerie navale, à Gavre, pres de Lorient), C. Dantin. Génie Civil, vol. 90, no. 24, June 11, 1927, pp. 569–572, 5 figs.

**Gantry-Cable.** Gantry-Cable Cranes for Storeyards (Brückenkabelkrane für Lagerplatzbedienung), K. Zapf. Fördertechnik u. Frachtverkehr, vol. 20, no. 1, Jan. 7, 1927, pp. 8–9, 3 figs.

**Gasoline-Electric.** Petrol Electric Mobile Crane. Indus. Mgmt. (Lond.), vol. 13, no. 1, Jan. 1926, pp. 7–9, 1 fig.

Petrol-Electric Mobile Crane. Ry. Gaz., vol. 44, no. 25, June 18, 1926, pp. 785–787, 5 figs.

**Gear Drive.** Worm Drive for Steel Mill Units. Iron Age, vol. 119, no. 22, June 2, 1927, pp. 1603–1604, 1 fig.

**Girder Design.** The Economics of Crane Girder Design, E. G. Fiegehen. Engineer, vol. 143, no. 3711, Feb. 25, 1927, pp. 204–205, 1 fig.

**Girders.** The Selection of Rolled Steel Joists and Compounds for Crane Girders, E. G. Fiegehen. Mech. World, vol. 82, no. 2116, July 22, 1927, pp. 57–58, 4 figs.

**Grab Buckets.** A New Automatic Electric Grab Bucket (Nouvelle Benne automatique à Moteur électrique), F. Bravais. Génie Civil, vol. 89, no. 2, July 10, 1926, pp. 38–39, 5 figs.

**Hammer-Head.** Calculation of a Hammer-Head Crane of 150 (200) Tons Capacity (Berechnung eines Hammerkrans von 150 (200) t Tragfähigkeit), J. M. Bernhard. Praktischer Maschinen-Konstrukteur, vol. 59, nos. 23–24 and 25–26, June 12 and 26, pp. 238–245 and 262–266, 16 figs.

**Hydraulic Cargo.** Hydraulic Cargo Cranes on the Motor Liner Austurias. Engineer, vol. 141, no. 3665, Mar. 26, 1926, p. 364, 3 figs.

**Ingot Tongs.** The Gripping Force of Ingot Tongs, W. E. Wright. Engineering, vol. 123, no. 3190, Mar. 4, 1927, pp. 274–275, 6 figs.

**Jib.** New Jib Cranes for Harbor Work (Neue Einziehkrane für den Seehafenumschlag), C. Overbeck. Zeit. des Vereines deutscher Ingenieure, vol. 70, no. 3, Jan. 16, 1926, pp. 73–77, 13 figs.

Notes on the Design of Crane Jibs, E. G. Fiegehen. Mech. World, vol. 79, no. 2037, Jan. 15, 1926, pp. 48–50, 4 figs.

**Jib, Traveling.** A New Type of "Toplis" Level-Luffing Crane. Engineer, vol. 141, no. 3673, June 4, 1926, p. 589, 3 figs.

**Level-Luffing.** The Toplis Level-Luffing Crane. Engineering, vol. 121, no. 3137, Feb. 12, 1926, pp. 200–202, 16 figs. partly on supp. plate.

**Load Brakes for A.C. Motors.** Solenoid Load Brakes for Wound-Rotor Alternating-Current Motors, H. H. Vernon. Gen. Elec. Rev., vol. 29, no. 4, Apr. 1926, pp. 268–270, 3 figs.

**Locomotive.** A Locomotive Crane for Lifting 120 Tons, E. Altschul. Brown Boveri Rev., vol. 13, no. 12, Dec. 1926, pp. 279–282, 6 figs.

Economic Utilization of Cranes in Locomotive Shops (Wirtschaftliche Ausnutzung der Hebekrane in Lokomotivausbesserungswerken), J. Franke. Organ für die Fortschritte des Eisenbahnwesens, vol. 81, no. 22, Nov. 30, 1926, pp. 450–453, 9 figs.

50-Ton Overhead Traveling Cranes, Horwich Works, L.M.S.R. Ry. Gaz., vol. 45, no. 27, Dec. 31, 1926, p. 787, 1 fig.

Traveling Bridge of 120 Tons (Pont roulant de 120 tonnes), M. Favre. Bul. Technique de la Suisse Romande, vol. 51, no. 26, Dec. 19, 1925, pp. 313–318, 5 figs.

**Locomotive Coaling.** Locomotive Coaling. Eng. Progress, vol. 7, no. 12, Dec. 1926, pp. 337–338, 2 figs.

**Motor Control.** Speed Control of Electric Crane Motors, A. C. Barson. Elec. Times, vol. 70, no. 1833, Dec. 9, 1926, pp. 713–714.

**Motor-Control Systems.** Special Control Systems for Cranes and Hoisting Appliances Equipped with Brown Boveri Single-Phase Commutator Motors, E. Altschul. Brown Boveri Rev., vol. 14, nos. 2 and 3, Feb. and Mar., 1927, pp. 61–65 and 86–89, 20 figs.

**Motor Rating.** Rating of Crane Motors (Die Leistungsbewertung bei Kranmotoren), C. Schiebeler. Electrotechnik u. Maschinenbau, vol. 44, no. 33, Aug. 15, 1926, pp. 604–606, 6 figs.

**Overhead Electric.** Rules for the Safe Operation of Electric Overhead Traveling Cranes. Iron & Steel Engr., vol. 3, no. 6, June 1926, p. 223.

**Plate-Glass Transportation.** Cranes for Transportation of Plate Glass (Glasscheiben-Transportkrane). Sprechsaal, vol. 60, no. 18, May 5, 1927, pp. 321–322, 2 figs.

**Plate-Lifting.** Plate-Lifting Cranes with Suction Attachment. Indus. Mgmt. (Lond.), vol. 14, no. 5, May 1927, pp. 163–164, 4 figs.

**Portable.** The Economical Disposition of Ballast in Portable Cranes, E. G. Fiegehen. Mech. World, vol. 81, no. 2109, June 3, 1927, pp. 389–390, 6 figs.

**Portal.** New Portal Cranes for the Kaiser Dock of the City of Dantzic, F. Woeste. Eng. Progress, vol. 7, no. 11, Nov. 1926, pp. 292–293, 2 figs.

**Power.** Power Cranes (Krane mit eigener Kraftquelle), F. Woeste. Zeit. des Vereines deutscher Ingenieure, vol. 70, no. 9, Feb. 27, 1926, pp. 291–296, 17 figs.

**Railway Storage-Battery.** Storage-Battery Rail Cranes (Akkumulator-Kranfahrzeuge), W. Rödiger. Fördertechnik u. Frachtverkehr, vol. 19, nos. 18 and 19, Sept. 3 and 17, 1926, pp. 269–271 and 291–293, 12 figs.

**Railway Wrecking.** Railway Breakdown Crane Design, E. K. Wright. Mech. World, vol. 81, no. 2088, Jan. 7, 1927, p. 6, 1 fig.

Railway Breakdown Cranes, E. G. Fiegehen. Ry. Engr., vol. 48, no. 572, Sept. 1927, pp. 330–331 and 333.

**Shaft Bearings.** Shaft Bearings in Crane Construction (Wälzlager im Kranbau), Müller. Fördertechnik u. Frachtverkehr, vol. 20, no. 12, June 10, 1927, pp. 216–218, 11 figs.

**Shipbuilding.** Slip-Crane Plant of a Rhenish Shipyard. Eng. Progress, vol. 7, no. 10, Oct. 1926, p. 260, 2 figs.

The Crane Equipment of Shipbuilding Berths, E. Smith. Shipbldg. & Shipg. Rec., vol. 27, no. 14, Apr. 8, 1926, pp. 407–412, 12 figs.

**Slewing.** Dynamics of Moving Loads During Acceleration Period (Die dynamischen Vorgänge während der Beschleunigungsperiode bewegter Massen bei Drehkranen), J. M. Bernhard. Fördertechnik u. Frachtverkehr, vol. 19, nos. 21 and 22, Oct. 15 and 29, 1926, pp. 320–323 and 335–337, 7 figs.

The Forces Involved in the Slewing Motion of Power Cranes, E. G. Fiegehen. Engineering, vol. 121, no. 3146, Apr. 16, 1926, pp. 483–484, 2 figs.

**Slipways.** New Cranes for River Boat Slipways. Indus. Mgmt. (Lond.), vol. 13, no. 10, Oct. 1926, pp. 417–421, 6 figs.

**Speed-Limiting Brakes.** Centrifugal Speed-Limiting Brake, J. P. Hall. Mech. World, vol. 82, no. 2113, July 1, 1927, pp. 9–10, 4 figs.

**Steam.** The Power Plant of a Locomotive Steam Crane, E. G. Fiegehen. Engineering, vol. 123, no. 3183, Jan. 14, 1927, pp. 60–61.

**Steel Mills.** General Specifications for Electric Overhead Traveling Cranes—Heavy Duty Steel Mill Service. Iron & Steel Engr., vol. 4, no. 1, Jan. 1927, pp. 21–25.

**Storm Brakes.** Storm Brakes for Cranes and Transporters. Indus. Mgmt. (Lond.), vol. 13, no. 6, June 1926, pp. 239–240, 4 figs.

**Traveling.** Traveler Erects Heavy Trusses for Theatre Roof. Eng. News-Rec., vol. 96, no. 11, Mar. 18, 1926, pp. 454–455, 5 figs.

Traveling Cranes for Handling Freight Cars in Railway Terminal Yards, H. B. Dwight. Elec. Jl., vol. 23, no. 9, Sept. 1926, pp. 448–450, 3 figs.

**Truck.** Raising and Turning Superstructures by Means of Crane Trucks (Ausheben und Verschwenken von Ueberbauten mit Kranwagen), O. Miehlke. Bautechnik, vol. 4, no. 24, June 4, 1926, pp. 337–344, 13 figs.

**Turntable Arrangements.** Turntable Arrangements for Jib Cranes, E. G. Fiegehen. Mech. World, vol. 81, no. 2104, Apr. 29, 1927, pp. 299–300, 5 figs.

**Wharf and Warehouse.** Wharf and Warehouse Cranes, C. H. Woodfield. Elecn., vol. 97, no. 2535, Dec. 31, 1926, pp. 754–755 and 762, 3 figs.

# F

## FOUNDRIES

**Conveyor Systems.** Conveyor System, F. G. Steinebach. Foundry, vol. 54, no. 7, Apr. 1, 1926, pp. 256–261, 8 figs.

Conveyors Nearly Triple Output, F. L. Prentiss. Iron Age, vol. 117, no. 14, Apr. 8, 1926, pp. 977–982, 10 figs.

## FREIGHT HANDLING

**Automatic Unloaders.** Conveying Freight from Automatic Unloaders to Destination (Die Ueberführung Förderguts aus Selbstentladern an den Bestimmungsort), Walther. Fördertechnik u. Frachtverkehr, vol. 19, nos. 4 and 5, Feb. 19 and Mar. 5, 1926, pp. 38–39 and 59–61, 10 figs.

**Container System.** Scientific Transportation, W. P. Kellett. Soc. Automotive Engrs.—Jl., vol. 19, no. 6, Dec. 1926, pp. 563–568, 2 figs.

Scientific Transportation. Soc. Automotive Engrs.—Jl., vol. 21, no. 1, July 1927, pp. 77–81 and 106.

**Exceptional Loads.** Transport of Exceptional Loads, A. R. Polson. Inst. Transport—Jl., vol. 7, no. 5, Mar. 1926, pp. 259–265.

**Iron Ore.** Handling the Nation's Largest Concentrated Traffic, W. H. Hoyt. Ry. Age, vol. 81, no. 15, Oct. 9, 1926, pp. 673–674, 2 figs.

**Large-Scale.** Freight Handling on a Large Scale (Grossbetrieb im Eisenbahn-Güterverkehr), Kümmell. Zeit. des Vereines deutscher Ingenieure, vol. 70, no. 30, July 24, 1926, pp. 1011–1014, 4 figs.

**Mechanical Equipment.** Mechanizing Handling of Freight (Die Mechanisierung des Güterumschlags), D. Przygode. Glasers Annalen, vol. 98, nos. 6 and 7, Mar. 15 and Apr. 1, 1926, pp. 87–96 and 112–113, 18 figs.

**Monorail Loaders.** New Monorail Loader Saves Time and Money, M. A. Hall. Automotive Mfr., vol. 69, no. 2, May 1927, pp. 5–7, 2 figs.

**New York City.** Some Freight-Handling Problems of New York City, E. Church. Soc. Automotive Engrs.—Jl., vol. 19, no. 3, Sept. 1926, pp. 235–238.

**Perishable Freight.** Perishable Freight, H. F. Prince. Central Ry. Club—Official Proc., vol. 34, no. 4, Oct. 1926, pp. 2121–2142, 16 figs.

**Pottery Barrels and Casks.** Handling of Barrels and Casks of Pottery En Route, C. M. Bonnell, Jr. Ceramist, vol. 7, no. 3, Dec. 1925, pp. 150–165, 10 figs.

**Rail and Highway Transportation.** Coordination of Rail and Highway Freight Transportation Within the Terminal Area, F. J. Scarr. West. Soc. Engrs.—Jl., vol. 31, no. 4, Apr. 1926, pp. 128–134.

**Railway Costs.** Service, Consumption of Fuel and Time in Freight-Train Traffic (Leistungen, Betriebsstoff- und Zeitverbrauch im Güterzugverkehr), W. Richard. Verkehrstechnik, vol. 43, no. 29, July 16, 1926, pp. 459–463, 3 figs.

**Terminal Transfer.** Saving 100,000 Car Days a Year, G. E. Boyd. Ry. Rev., vol. 78, no. 26, June 26, 1926, pp. 1193–1198, 5 figs.

**Unboxed Shipments.** Reducing Shipping Costs, G. F. Bauer. Mfg. Industries, vol. 13, no. 5, May 1927, pp. 349–352, 5 figs.

# H

## HOISTS

**Applications.** Lifting and Shifting Machinery—Ancient and Modern Practice, C. H. Woodfield. Jl. Instn. of Engrs., vol. 37, Oct. 1926, pp. 1–21, 12 figs.

**Blocks.** A New Type of Electric Hoisting Block. Eng. Progress, vol. 8, no. 6, June 1927, pp. 145–146, 4 figs.

**Brakes.** Hoist Brakes (Betrachtungen über Hebzeugbremsen), Goldberger. Fördertechnik u. Frachtverkehr, vol. 20, no. 7, Apr. 1, 1927, pp. 136–140, 12 figs.

Safety Hoist Brake of New Type Has Many Advantages, C. H. S. Tupholme. Coal Age, vol. 31, no. 20, May 19, 1927, pp. 729–731, 2 figs.

**Electric.** Electric Hoist at Horne Copper Corporation. Can. Min. Jl., vol. 48, no. 34, Aug. 26, 1927, pp. 671–674.

**Grab-Bucket, Control.** Control for Alternating Current Grab-Bucket Hoists, J. A. Jackson. Gen. Elec. Rev., vol. 29, no. 9, Sept. 1926, pp. 642–645, 4 figs.

**Potentiometer Arrangement.** Potentiometer Arrangement for Hoists (Disposition en potentiometre pour engines de levage), J. Foerster. Revue Universelle des Mines, vol. 15, no. 1, July 1, 1927, pp. 5–14, 7 figs.

**Skip.** Electric Equipment for the Skip Hoist, C. P. Hamilton. Gen. Elec. Rev., vol. 29, no. 9, Sept. 1926, pp. 646–650, 4 figs.

New High-Power Skip Hoists in Coal Mines of Southern Illinois (Neu Kübelförderungen mit grossen Leistungen auf Schachtanlagen in Süd-Illinois), F. Herbst. Gluckauf, vol. 63, no. 19, May 7, 1927, pp. 673–681, 7 figs.

Portable Skip Hoist Loader, G. F. Zimmer. Indus. Mgmt. (Lond.), vol. 14, no. 3, Mar. 1927, pp. 79–81, 5 figs.

Skip Hoisting at Illinois Coal Mines, A. J. Hoskin. Indus. Mgmt. (Lond.), vol. 13, no. 4, Apr. 1926, pp. 163–167, 1 fig.

Skip Hoisting in Mining Practice (Die Kübelförderung im Bergwerkbetriebe), P. Walter. V.D.I. Zeit., vol. 71, no. 21, May 21, 1927, pp. 696–702, 32 figs.

**Skip Buckets.** The Tipping Phenomenon of Buckets in Skip Hoists (Der Kippvorgang des kippenden Kübels bei der Kübelförderung), P. Walter. Fördertechnik u. Frachtverkehr, vol. 19, nos. 2 and 4, Jan. 22 and Feb. 19, 1926, pp. 17–18 and 41–43, 14 figs.

# I

## INDUSTRIAL TRUCKS

**Automobile Manufacturing Plants.** How the Automotive Industries Have Put the Electric Industrial Truck to Work, H. J. Payne. Indus. Mgmt. (N. Y.), vol. 72, no. 2, Aug. 1926, pp. 88–95, 15 figs.

**Battery-Driven.** Modern Transport and Storage Methods, G. D. Ozanne. Indus. Mgmt. (Lond.), vol. 14, no. 6, June 1927, pp. 219–220, 2 figs.

**Control.** Control Equipment for Industrial Trucks, R. B. Hunter. Indus. Engr., vol. 84, no. 5, May 1926, pp. 219–224, 11 figs.

**Dispatching.** How the Westinghouse Plant Gets Maximum Service from Electric Industrial Trucks, R. E. Jansen. Indus. Mgmt. (N. Y.), vol. 74, no. 2, Aug. 1927, pp. 106–111, 11 figs.

**Electric.** Electric Trucks in the Locomotive Repair Shop, H. J. Payne. Ry. Elec. Engr., vol. 17, no. 1, Jan. 1926, pp. 21–23, 7 figs.

Factory Trucks and Cars (Les Chariots et les Tracteurs d'Usine), R. Gasquet. Revue Industrielle, vol. 56, nos. 2204 and 2205, July and Aug. 1926, pp. 289–294 and 342–346, 17 figs.

Field of Application and Savings Effected by Industrial Trucks, H. J. Payne. Elec. World, vol. 87, no. 24, June 12, 1926, pp. 1292–1294, 2 figs.

How Electric Industrial Truck and Tractor Equipment is Effecting Savings in the Iron and Steel Industry, H. J. Payne. Iron & Steel Engr., vol. 3, no. 6, June 1926, pp. 274–283, 10 figs.

Keeping Materials Handling Costs Moving Downward in the Rubber Plant, H. J. Payne. Indus. Mgmt. (N. Y.), vol. 71, no. 1, Jan. 1926, pp. 40–43, 7 figs.

Saving in Foundry Handling with the Electric Industrial Truck, H. J. Payne. Am. Foundrymen's Assn.—Preprint, no. 11, for mtg. Sept. 27–Oct. 1, 1926, 16 pp., 10 figs.

The Expanding Uses of the Electrical Industrial Truck, H. J. Payne. Factory, vol. 36, no. 6, June 1926, pp. 1035, 1130, 1134 and 1138.

The Use of Battery Electric Trucks as a Means of Reducing Handling Costs at the Gas Works, S. M. Hills. Gas Engr., vol. 43, no. 609, Jan. 1927, pp. 9–10 and 12, 3 figs.

**Foundries.** Trucks Handle Materials in the Foundry, C. C. Hermann. Iron Trade Rev., vol. 78, no. 7, Feb. 18, 1926, pp. 455–456, 8 figs.

**Freight Stations.** Electric Trucks at D. L. & W. Car Float Freight Stations, R. M. White. Ry. Age, vol. 81, no. 16, Oct. 16, 1926, pp. 716–718, 6 figs.

# Sugar-Warehouse Conveying Systems

By JOSEPH T. BUZZO,[1] SAN FRANCISCO, CALIF.

*In this paper the author describes conveying equipment installed at the Crockett, Calif., plant of the California and Hawaiian Sugar Refining Corp. First, a general description of the plant layout is given, together with an explanation of certain conditions which demand large storage facilities for both raw and refined sugar. Among the types of conveyors described are belt conveyors, depressed floor conveyors, slat conveyors, a specially designed screw conveyor, and various portable and semi-portable conveyors. The duty to be performed by each of these types is mentioned, and the maintenance problem is discussed. An interesting weighing conveyor, which receives the bagged sugar directly from the steamer, is described. A part of the paper deals in an explanatory manner with the very interesting central-control board, through which the entire system is under instant control. An interesting comparison of manual and conveyor handling is given, with the figures well in favor of the latter method.*

CROCKETT, Calif., is situated about thirty miles east of San Francisco on Carquinez Straits, the connecting link between San Pablo and Suisun Bays. The plant of the California and Hawaiian Sugar Refining Corporation has at Crockett an ideal manufacturing location, for here, literally, "rail and water meet." Along a water frontage of approximately 3000 ft. there is a depth of 40 to 50 ft., and vessels may safely dock at any point for receiving or discharging cargoes. The main line of the Southern Pacific Company runs on the south side of the refinery, where there are ample facilities for switching and for loading and shipping the finished product.

The main warehouse, 870 ft. long by 290 ft. wide, and the auxiliary warehouse, 320 by 160 ft., have a combined storage capacity of 135,000 tons of sugar. Such extensive storage facilities are required because of special conditions surrounding the company's business. Into these warehouses is gathered the raw sugar from 31 Hawaiian plantations. With the exception of a short shut down at the end of the year, for overhauling, the refinery operates continuously at a uniform rate of 2200 to 2400 tons per day. The plantations, however, produce the raw sugar during a much shorter season, governed by the ripening of the cane, and the resulting accumulation of raws must be stored for subsequent refining. Also, in order to secure the minimum manufacturing cost, the refinery, as mentioned, operates at a uniform rate throughout the year. Therefore storage space must be provided for refined sugar when the market fails to absorb it as rapidly as it is produced.

The incoming raw sugar may be sent direct from dock to refinery or into the warehouse for storage, whence later it must be transferred to the refinery. The finished product must in turn be delivered to the warehouse either for direct shipment or into storage for subsequent shipment by rail or water. The economical accomplishment of these various manipulations calls for a comprehensive conveying system of great flexibility. It is the province of this paper to offer a brief description of the manner in which the company has worked out this problem.

## General Arrangement of Conveyors

It is difficult to concisely describe the system with its interlocking features so that the arrangement may be clearly grasped. A study of Fig. 1, which is an ideal cross section of the main warehouse, will greatly assist. Broadly, there is a complete system for transferring within the warehouse, this system being connected to the refinery by two belt conveyors which serve the double purpose of taking the raw sugar to the refinery and of returning the refined product to the warehouse system for distribution to storage or to shipping points. In addition, a separate conveying system is provided for transporting barrels and boxes to the warehouse.

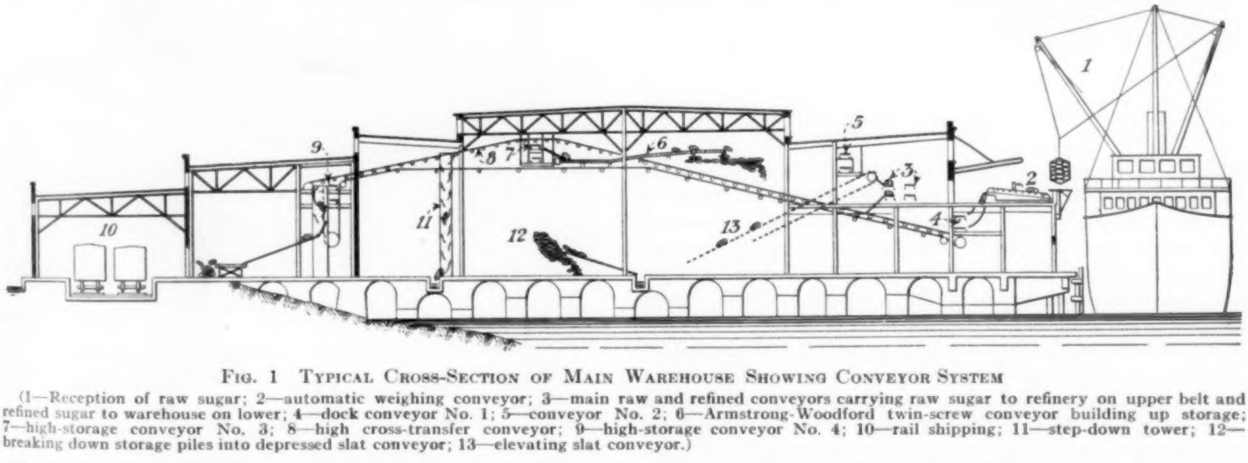

Fig. 1 Typical Cross-Section of Main Warehouse Showing Conveyor System

(1—Reception of raw sugar; 2—automatic weighing conveyor; 3—main raw and refined conveyors carrying raw sugar to refinery on upper belt and refined sugar to warehouse on lower; 4—dock conveyor No. 1; 5—conveyor No. 2; 6—Armstrong-Woodford twin-screw conveyor building up storage; 7—high-storage conveyor No. 3; 8—high cross-transfer conveyor; 9—high-storage conveyor No. 4; 10—rail shipping; 11—step-down tower; 12—breaking down storage piles into depressed slat conveyor; 13—elevating slat conveyor.)

Within the warehouse there are four belt conveyors and two depressed floor slat conveyors running from one end to the other. These are in turn served by four cross-belts, two inclined slat conveyors, and miscellaneous portable or semi-portable conveyors, chutes, etc., which transfer the product from one to another of the main units.

Conveyor No. 1 (Fig. 1), known as the "dock conveyor," located just below the second floor on the water front, receives the raw sugar from the steamers. It is arranged so that both the upper and the lower, or return side, may be used, thus providing transfer in both directions. All of the main belt conveyors are designed in this same way to convey simultaneously on either the upper or the return side of the belt.

Conveyor No. 2 is used primarily for the refined product and

[1] Mechanical Engineer, Construction Department, California and Hawaiian Sugar Refining Corp., San Francisco, Calif.

Presented at the Seattle Meeting, Seattle, Wash., August 29 to 31, 1927, of The American Society of Mechanical Engineers.

delivers to any desired point along the waterfront, either for trucking to the steamers or for storage on the first and second floors. In emergency it may also be used for the transfer of raw sugar leading to the refinery or to storage on the second floor.

Conveyor No. 3, known as the "high-storage conveyor," is used for delivering either raw or refined sugar to storage piles.

Conveyor No. 4 is for distribution of the finished product for rail shipments.

The two depressed floor slat conveyors gather raw sugar from storage and by inclined slat conveyors elevate to what are called the "main raw and refined conveyors," which lead to and from the refinery.

### Control

Fig. 2 is a view of that section of the warehouse where the system converges for delivery to the two main raw and refined conveyors leading to the refinery. At this point a "control operator" is placed. His station is located at a strategic point where he has an uninterrupted view of all the conveyors in this section, supplemented by telephone and bell-signal communication with all parts of the warehouse. Here the entire system of 32 individual units is under remote control. The specially designed control board is shown in Fig. 3. On the bench are located remote-control start and stop switches for all units. These control automatic starters of the transformer and "across-the-line" type, mounted on centrally located panel boards in each section of the warehouse. At each switch a red light shows operation or a green light indicates that the conveyor is idle. Specially marked rubber caps, fitting over the remote-control buttons, indicate the combination of conveyors in a complete train. Above the bench are the signal and instrument panels. The operating signals are given by colored lights behind transparencies supplemented with bell alarms. Throughout the conveying system are emergency-stop push buttons. When a unit is so stopped a red light automatically illuminates the transparency for that unit and a bell alarm sounds. Also, the red light on the bench goes out and the green light comes on. To prevent blockades, the control operator immediately stops the other conveyors which feed this unit and stands by ready to restore operation on signal. In case a motor kicks out through overload, the transparency takes a green illumination and a bell alarm sounds.

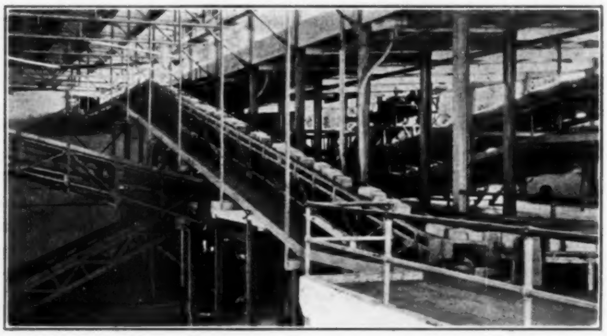

Fig. 2 Principal Junction Point of Conveyors in Warehouse
(Left, elevating slat conveyors and high cross-belts; center, specialty conveyor carrying boxes; right, raw and refined belts running to and from refinery.)

Provision is made on the panels for adding ammeters which will act for the control operator as indicators to show normal and abnormal operation, and make it possible to arrange for the correction of improper conditions before serious trouble develops.

Wherever possible, belt conveyors are used in preference to the slat design. These have untroughed belts 36 in. wide, a width which permits the bags to lie in any position. The belts are seven-ply with best quality friction or cement, and are finished with $^3/_{64}$-in. rubber cover, both sides. The fabric is special 32-oz. duck, having, per inch, 26 strands of eight cords each in the warp and 16 strands of five cords each in the filler.

Extensions to the system have been added from year to year, and it has been the practice to place the new belting on the most severe service, transferring the used belting to a lighter duty. This has so prolonged the life that there has been no discard and the oldest belt has now been in continuous service over twenty years. With the completion of the system, however, replacements will become necessary.

### Belt Conveyors

The longest conveyor is about 800 ft. between pulleys, with an actual belt length of 1724 ft. The operating speed is about 250 ft. per min., determined by operating conditions and not by the carrying capacity of the conveyors. So far it has been impossible to provide a continuous stream of bags, owing to the fact that delivery from the steamer holds it in batches. A speed beyond the theoretical is, therefore, required to properly space the bags from these batches. Also, at the speeds employed, the bags are switched off the belts with minimum difficulty.

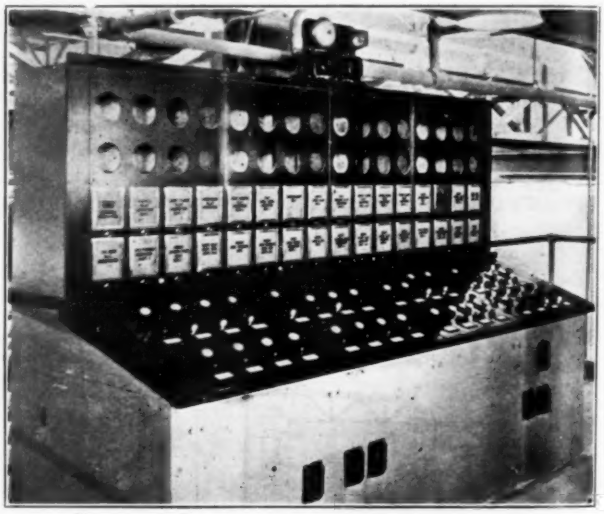

Fig. 3 The Control Board

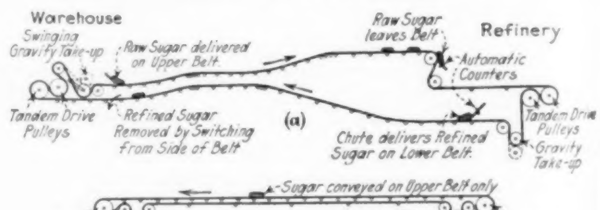

Fig. 4 Diagrams of Belt Conveyors Illustrating Two Arrangements for Gravity Take-Up
(a) Raw and refined conveyors, typical of belts traveling in one direction and conveying both ways simultaneously.
(b) Reversible belt conveyor with drive and take-up at both ends.

The longer belts are driven at both ends with the two motors electrically interconnected and, for heavy drives, rubber-covered drive pulleys are provided in tandem. The length of the belts

is affected by weather conditions. To compensate for this, and especially to take care of the elongation at starting, gravity take-ups are installed. On belts running in only one direction these are placed (see Fig. 4) at the points of least tension, on the upper side at one end and on the return side at the opposite end. On reversible belts both take-ups are located on the lower side and only one functions, depending upon the direction of travel.

The belts are supported on plain rollers with hardwood blocks for bearings. Because of the thousands of rollers involved, an extensive investigation has been made to compare the standard with the ball-bearing types. While the latter were, of course, more economical as to power consumption, they failed to stand up under severe service. Although the hardwood bearings give no trouble and are exceedingly cheap, it is debatable whether metal journals would not be superior.

With the system under discussion, it is, in many cases, necessary to switch containers from the belts. This is accomplished by means of a board diagonally disposed over the belt. When in a raised position the bags may pass through, but they are pushed off when the switch is lowered. Brands which are to go to different destinations are sorted on the conveyors by means of these switches.

### Slat-Type Conveyors

In the case of the depressed floor conveyors and inclined elevators, the belt design would be impracticable, and the slat type is used. Wooden slats 30 in. long by $3\frac{1}{2}$ in. by $1\frac{3}{8}$ in. are bolted to two strands of No. 212 Griplock roller chain which travel in angle-iron tracks. For strength and freedom from splintering, the slats are made of hardwood. As there is little stretch, short take-ups are suitable. Adjustments can also be easily secured by removal of a slat with its attachment links. In the case of the depressed conveyors a single scraper projecting beyond the surface of the slats automatically prevents accumulation in the pits of spillage from broken raw-sugar bags. This is scraped to the tail pit from which it is readily removed.

On the incline conveyors, three consecutive slats in each group of ten are of steel plate, affording a depression so that the following wooden slat acts as a lifter. With this design a 50 per cent inclination is practicable.

Slat conveyors for given lengths consume much more power than does the belt design. The longest conveyor, with the type of chain on which this company standardizes, is 300 ft. between centers, and a 20-hp. motor is required.

### Discharging Cargo

Seventeen vessels of the Matson Navigation Company bring the raw sugar to Crockett from the Hawaiian Islands. The largest of the fleet are the sister ships, *Manukai* and *Manulani*, which carry 14,000 tons each. Discharge is by slings of fifteen bags, or from 1500 to 1900 lb. The loads are dropped on stevedores' tables on the upper deck of the dock (see Fig. 1). Formerly all bags were hand trucked from this point over platform scales to the conveyor. With this method of discharge, 20 truckers per hatch could handle but 675 tons in eight hours.

### Conveyor Scales

Three years ago specially designed conveyor scales were developed and installed, and now one man replaces the 20 truckers. At the same time, the rate of discharge, due principally to the use of these conveyor scales, has increased from 675 to 1000 tons. The total crew for a hatch consists of 22 men. On shore there are six table men, two weighers, and one switchman; on the steamer, a foreman, a winch driver, a hatch tender, and ten stevedores in the hold. These scales are shown in Fig. 5. Four units of two scales each are installed. Usually, however, discharge is from two hatches only, and never from more than three. The conveyor is mounted on a platform scale which in turn is carried by a steel frame work fitted with car wheels. Tracks laid along the dock make it possible to shift the units, for spotting opposite ship's hatches. Each unit is provided with jacks for accurately leveling the scale. Provision is made for quickly taking scale checks. A set of test weights is so mounted that by moving a lever they may be placed on the scale or removed. A revolving brush cleans the belt, immediately removing all loose sugar spillage; otherwise the accuracy of the weighing would be impaired. The design permits taking weights in transit, although with a push button control the operator can, when necessary, stop within a few inches. Careful checking has conclusively proved the accuracy of this method of weighing, and the weights are accepted by both the refinery and the plantations as the basis for purchase.

Fig. 5 Duplex Scale Conveyor with Canopy Removed

### Progress of Material Through Plant

The raw sugar required for immediate process is delivered by the conveyor direct to the refinery, and the balance goes to storage. The switchman working at the end of the scale conveyors operates a chute to divide the bags between the upper and lower sides of the dock conveyor, No. 1, Fig. 1, for the refinery and storage, respectively.

The bags on the upper belt are switched to a cross-conveyor, from which they are delivered to one or the other of the depressed-slat conveyors, thence by way of the inclined slats to the main raw and refined belts leading into the refinery.

This is the standard routing of the sugar, although in emergencies, caused for example by the shut down of a unit, there are several other combinations of conveyors which can be used. It is even possible to reach either of the main raw and refined conveyors entirely by the belt system and without the use of the depressed floor slats.

The raw-refined conveyors are so named because they carry raw sugar on the upper side to the refinery, and on the lower side return the refined product to the warehouses. Fig. 4 shows in outline the plan of these conveyors. Duplicate installation minimizes the danger of complete stoppage of the flow of sugar, which if prolonged would be followed by a costly shutdown of the plant. In actual fact, however, as a result of rugged construction and careful maintenance, it has never been necessary to shut down either unit for more than an hour or two.

Each belt conveyor discharges its load of bags to the refinery upon what is known as the "cut-in conveyor." This is a slat conveyor placed at table height over a large storage bin covered with steel grating. Workmen along these slat conveyors open these bags and empty them through the grating into the bin.

All of the raw bags are automatically counted by an electric

counter as they leave the belt conveyor. The discharge chute leading to the cut-in conveyor is fitted with a trigger which is deflected by each passing bag. This trigger actuates the electric contacts by means of a shaft and cam which is returned to the open position by a spring. In order to avoid chattering, due to rebounds which would result in double count, an electromagnet is used. The magnetic circuit is completed through the cam which acts as an armature.

Thus the bags which are placed by the stevedores on the scale conveyors at the dock travel a distance of 1500 to 1600 feet with no manual handling until they reach the cut-in conveyors at the refinery.

Those bags of raw sugar which are to go into storage are sent by the switchman at the end of the conveyor scales to the lower side of the dock conveyor, No. 1, Fig. 1, from which they are in turn transferred by one of the high cross-belts to the main-

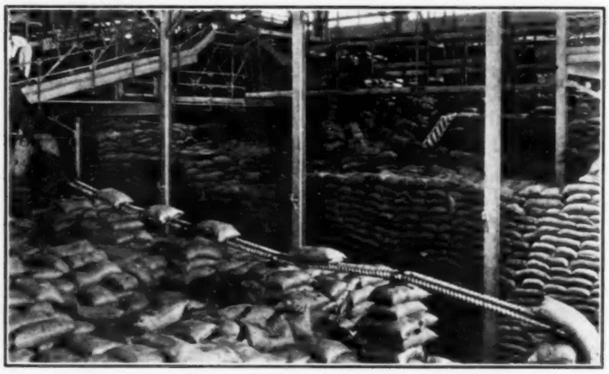

Fig. 6 Armstrong-Woodford Twin-Screw Conveyor
(Conveying from high cross-conveyor to storage pile at upper right—high-storage conveyor.)

storage conveyor, No. 3, Fig. 1. At the desired destination they are switched off and by chute or portable conveyor carried to the proper point for placing into the storage pile by hand. These piles are carried seventy bags high, about forty feet, the bags being placed in an orderly manner to secure a rectangular pile, to which stability is given by making every fifth course a header.

## Twin-Screw Conveyor

Fig. 6 shows raw sugar going into a storage with the use of a special portable conveyor, the patented invention of two of the Company's engineers. In this machine, known as the Armstrong-Woodford twin-screw conveyor, two parallel members of light tubing wound with a coarse-pitched right- and left-hand thread perform the carrying operations. Sections 8 ft. long and connected at bearing points by universal joints, permit positioning over irregular surfaces. The drive end consists of a motor with a double right and left worm-gear set. The two screws operate at 200 r.p.m., rotating inward, and convey at the rate of 100 ft. per min. Sections weigh but 55 lb. each, and the length can be increased quickly and easily, a section at a time, from 8 ft. minimum to 60 ft. or more. The conveyor will deliver downward at almost any angle and will elevate at from 20 to 40 deg., depending upon the shape and pitch of the thread. On sugar piling, two of these units have saved five men.

## Chutes and Step Towers

In Fig. 6 the bags are shown being delivered to the twin-screw conveyor by a wooden chute. The elevation of the high-storage conveyor is 36 ft. above the floor level. In starting sugar piles and also for transferring from the high conveyor to floor conveyors, the use of such chutes is awkward and space-consuming. Spiral conveyors have been used, and for fixed installations are preferable to the straight chutes as they require less floor space. This design has been abandoned, however, except for handling barrels and boxes. In Fig. 7 may be seen a canvas tube which is serviceable and has the advantage of light weight. After considerable experimental investigation, however, the company is gradually standardizing on "step towers," one of which is indicated in Fig. 1. This type has been used in other industries, both for the lowering of loose material, such as coal and rock, and also for sacked material. It consists essentially of curved baffles alternately opposed and mounted in a substantial framework. This appliance overcomes many of the objectionable features of the other types. It occupies little floor space and the baffles so check the acceleration of the falling bags that, in a drop of 30 feet, the speed is not perceptibly increased.

In completing a storage pile it is the present custom to leave, at the top, a channel wide enough to receive a straight wooden chute. When the pile is to be torn down, chutes are placed so as to deliver the bags to the depressed floor conveyors for delivery to the refinery in the same manner as has been described. The chutes may terminate in a portable conveyor in order to reach the

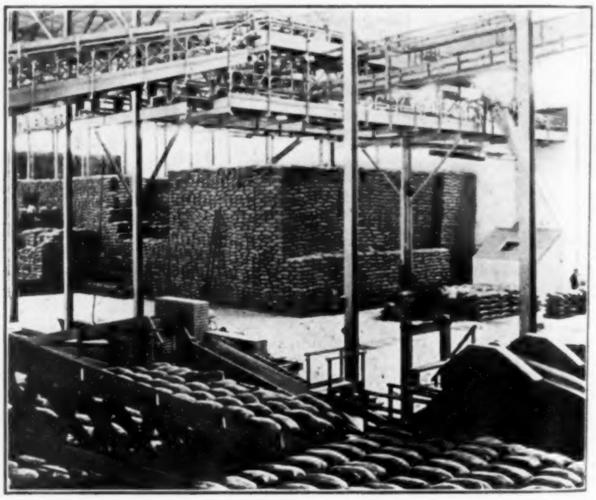

Fig. 7 Sugar in Storage
(Above, junction of high cross and high-storage belts; below, depressed conveyor delivering to inclined slat conveyor; right, canvas tube for lowering bags from overhead conveyors.)

depressed floor conveyor, and when the grade becomes too low the removal may be completed entirely with portable conveyors or by trucking.

Aside from the fact that with this method a few men can handle a considerable tonnage, the company believes it has little merit. By constant investigation, the company seeks improved methods which may not only be more efficient but which will also result in less damage to containers and will be less hazardous to the employee.

Having discussed the transfer of raw sugar from the steamer, both to the refinery and into storage, with subsequent transfer to the refinery, the author will now pass to the handling of the refined product.

## Handling the Finished Product

The last refinery operation is the sewing of the bags. Chutes convey these to the return side of the main raw and refined conveyors, from which they may be sent to one of four destinations. For water shipment, transfer to the dock conveyor, No. 1, Fig. 1, permits distribution for direct trucking to steamers or

barges, or the sugar may be transferred to conveyor No. 2 for preliminary storage at any point along the water front, on the first or second floor. By high cross-conveyors, Fig. 7, it may be transferred to the high-storage conveyor and delivered, as in the case of the raw sugar, into high-storage piles. Finally, by the same high-cross conveyors, it may be transferred to conveyor No. 4, Fig. 1, by which distribution is made through the train shed, either for preliminary storage or directly to freight cars.

Breaking down refined sugar piles is accomplished in the same manner as with the raw sugar, excepting that more care is exercised to prevent breaking of containers.

The entire discussion so far has been confined to the handling of sugar in bags. This applies to all of the incoming raws and to about 88 per cent of the finished product. The balance of the output is shipped in barrels, half barrels, boxes, and cartons, the latter packed in wooden cases For the transportation of the sugar in these hard containers an entirely independent installation is required, which, however, possesses no especially novel features. Part of the system may be seen in Fig. 2. For those straight-line sections which are nearly horizontal or are inclined upward, power-driven slat conveyors are used. Where the path changes direction, or is downward with a sufficient gradient, ball-bearing roller conveyors are used, and spirals are installed for dropping from one floor to another. Gravity systems, for the best results, should of course be designed for the particular shape and weight of package to be transported. However, the individual quantities to be handled at the refinery are too small to justify separate conveying installations, and therefore all are handled with reasonable satisfaction on the single system described in the preceding pages.

## Conclusions

While many features, both of equipment and methods, which have been briefly discussed in the foregoing paper, are no doubt adaptable to other similar fields, nevertheless, the conditions as a whole at Crockett are so peculiar to this plant that any cost data would be meaningless.

The main conveying systems have proved, generally, most satisfactory. The products are transferred easily and, because of the distances involved, it is believed at a lower cost than would be met with any other mode of transportation. Special auxiliary equipment which has been developed, such as the step towers, twin-screw conveyors, conveying scales, etc., have proved their worth. However, the company and its engineers consider that there is a great opportunity for further economy in handling the products after they leave the main conveying systems. With the practical completion of an extensive construction program which has occupied a period of years, it is now possible to give more concentrated attention to the refinements of this work.

Economies may probably be secured through a more extended application of the twin-screw conveyor and of the step tower. A portable type of step tower used in combination with the twin-screw conveyor may prove of much value in building up and tearing down storage piles. In these and other ways it is expected that appreciable economies may be realized, and the engineering department in cooperation with the warehouse department is carefully investigating this attractive field.

# Operating Costs of Electric Industrial Trucks and Tractors

By C. B. CROCKETT[1] and H. J. PAYNE,[1] NEW YORK, N. Y.

*The authors attempt to show how direct and indirect costs of a materials-handling system may be classified and estimated, and apply the methods described to the question of operation of electric trucks. The direct costs of operation are here divided into fixed charges and operating charges, both of which are enumerated and, where possible, estimated. Factors affecting the costs are likewise enumerated, and actual figures of cost of operation taken from several plants are presented, and the savings due to truck operation pointed out.*

THIS paper has been prepared to present outstanding economic features of the subject. The authors have attempted to define the different costs as they are most generally accepted in industrial plants, to reproduce fair average figures from actual performance data, and to set forth sufficient actual records to illustrate the effect upon costs of varying plant conditions.

The subject of indirect costs and savings is briefly discussed, and the major items are identified so that executives considering the purchase of new equipment may find here data that are of direct value in explaining the factors to be considered.

Underlying the use of the electric industrial truck or tractor is the fundamental principle which has characterized the phenomenal growth of America's manufacturing business, the principle of the maximum use of mechanical energy for every wage earner. Figures recently published by the Government Bureau of Foreign and Domestic Commerce reveal that since 1870 the value *per worker* added to goods by manufacture has increased 397 per cent, while the mechanical energy available per worker has increased 371 per cent.

Increased production goes hand in hand with the application of mechanical energy to manufacture.

Modern management applies the searchlight of cost accounting on manufacturing processes and the handling of material in the plant alike. Uniformity of work, however, and similarity of conditions characterize the manufacturing process but are conspicuous by their absence in the field of materials handling. Net yearly cost per unit moved is the goal which has been set, but that goal is difficult and well-nigh impossible of attainment. Costs per foot-pound or ton-mile moved are theoretically the most desirable, but practical limitations have made the cost per ton moved, cost per load moved, or cost per day more generally accepted units.

Costs of any mobile materials-handling system may be generally classified as "direct" and "indirect," and must be given equal consideration. The direct charges, both fixed and operating, are those incurred in the operation of the system itself. The indirect costs are those incurred in other processes or departments but which are influenced by and attributed to the materials-handling system.

The direct costs of operation of electric trucks may be divided into "fixed charges" and "operating charges."

The first group, assuming proper maintenance and properly chosen equipment, are independent of the type of work or number of hours used per day unless it be a question of 8- or 24-hour service, in which latter case depreciation will of course be more rapid.

The fixed charges are easily defined and hence readily available. They include:

1 *Depreciation on Truck or Tractor* is almost always the cost of the truck or tractor divided by the estimated life and charged off periodically. Truck and tractor prices vary from $1100 to $3800 with average lives of 8 to 14 years, the resulting average depreciation charges being about $300 yearly.

2 *Depreciation on Storage Battery* is arrived at in the same manner as for the truck, a time basis being used. First costs of batteries vary from $250 to $1500, with a life dependent upon the type selected. Average depreciation charges may be taken as $200.

3 *Depreciation on Charging Equipment* is similar to the items above, costs varying from $150 to $300 with lives of 15 to 20 years. Annual charges average $10 to $15.

4 *Interest, Insurance, and Storage Charges* for the above are usually grouped and figured as a straight per cent yearly on the first cost of the equipment. This figure is generally taken as 7 per cent, being 4 per cent for insurance and taxes, and 6 per cent interest less 3 per cent interest on depreciation reserve.

Operating expenses are divided in several manners, but the variations are of minor importance, the usual classification being along these lines:

1 *Power.* This includes the kilowatt-hours of energy plus any labor charges for battery charging. The average kilowatt-hour rate when the charging is done on off-peak hours is about 2 cents per kw-hr. A careful examination of the rate structure of the company supplying energy should be made to determine the net cost per kw-hr., as battery load may improve the load or power factor so that a general improvement is made in the users' rate. Separate metering for battery charging is in general preferable. The labor for charging varies with the type of equipment used and must be correlated with the fixed charges of the equipment. Approximate figures for this item run about 19 kw-hr. hours at 2 cents an hour or 35 cents per eight-hour day.

2 *Maintenance.* Maintenance is preferably divided into three subdivisions, namely, truck, battery, and charging equipment so that total costs on each item may be reached. Items generally included under this heading are oil, grease, distilled water, flushing battery, small parts, tire replacements, periodic inspection, and minor repairs. Major replacements or rebuilding should be charged against the reserve for depreciation as these latter will increase the life of the truck.

Using the averages for the different items above we arrive at the following summary of average yearly costs:

| | |
|---|---|
| Depreciation of truck | $300.00 |
| Depreciation of battery | 200.00 |
| Depreciation of charging equipment | 15.00 |
| Interest, insurance, and storage charges | 245.00 |
| Power | 225.00 |
| Maintenance and repairs | 225.00 |
| Total equipment cost | $1210.00 |

or $50^1/_2$ cents per hour on a basis of 300-eight-hour days per year.

It is seen that a large proportion of the cost lies in the fixed charges on the equipment. A graphical analysis has been made

[1] The Society for Electrical Development, Inc., New York, N. Y. Assoc-Mem. A.S.M.E.

Contributed by the Materials Handling Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

in Fig. 1 of the Appendix, in which chart these costs are compared with those of gasoline equipment whose fixed charges are smaller but operating expenses higher. This analysis gives the cost per number of hours in service per year.

Quantitative data on costs are not readily available, but the following actual cases have been chosen rather because it is believed that all direct costs have been included than for any comparison with other methods or savings effected.

Complete and accurate operating costs have been made available by a southern firm handling marine freight. The year's record for one truck and 3 men is as follows:

| Production | |
|---|---|
| Tons handled | 19866 |
| Man-hours | 7367 |
| Labor cost | $3502 |
| Tons per man-hour | 2.70 |
| Labor cost per ton | $0.176 |
| Equipment cost per ton | 0.063 |
| Total cost per ton | $0.239 |
| Saving per ton | $0.103 |

| Costs | | |
|---|---|---|
| Power | $379.10 | |
| Labor charging | 174.22 | |
| Flush, oil and grease | 82.03 | |
| Repair labor | 97.84 | |
| Repair material | 54.48 | |
| Total operating cost | | $787.67 |
| Truck depreciation | $150.00 | |
| Battery and charging equipment depreciation | 182.00 | |
| Interest on investment | 125.00 | |
| Total fixed charges | | 457.00 |
| Total equipment cost | | $1244.67 = 52 cents per hr. |

The power costs on this installation seem particularly high, but this implies the heavy use of the truck. The saving of $0.103 amounts to $2036 annually.

Power costs show extreme variations, and in contrast to the figures above are the costs of a truck operating in a steel plant where the power generated is a by-product of the main operation.

| | |
|---|---|
| Power | $ 36.00 |
| Labor and repairs | 300.00 |
| Truck depreciation | 180.00 |
| Battery and charging-equipment depreciation | 192.00 |
| Annual equipment cost | $708.00 |

A foundry operating 24 electric lift trucks found the average yearly cost per truck to be as follows:

| | |
|---|---|
| Truck depreciation | $135.00 |
| Battery depreciation | 97.00 |
| Charging-equipment depreciation | 15.00 |
| Interest on investment | 119.00 |
| Power at 1 cent per kilowatt-hour | 50.00 |
| Repair and maintenance—labor | 81.00 |
| Repair and maintenance—material | 138.00 |
| Oil and grease | 6.00 |
| Annual equipment cost | $641.00 |

A New England leather concern operates a fleet of electric trucks under severe conditions. Hauls are partly over city streets and partly over the slippery runways of various departments of the tannery. Occasionally trucks drop from runways to tanning vats, but without serious consequences other than necessity for a few hours drying out. Such conditions are reflected in the costs, but to a surprisingly small degree.

| | |
|---|---|
| Power | $183.00 |
| Labor for charging | 75.00 |
| Repair and maintenance material | 459.00 |
| Repair and maintenance—labor | 186.00 |
| Overhead on investment | 597.00 |
| Annual equipment cost | $1500.00 |

A large automobile concern present their costs in a form slightly different from that used above, but it presents an excellent example of those indirect savings which this company has been able to evaluate. These costs show a comparison between old method of handling sheet steel and the use of a 10-ton lift truck which was developed by the company for handling sheets in bundles of that weight.

The figures:

| | Cost per ton: Old method | Cost per ton: New method | Saving by new method |
|---|---|---|---|
| Damage to sheets chargeable to steel mill | $1.035 | $0.261 | $0.774 |
| Damage to sheets chargeable to railroad | 2.688 | 0.066 | 2.622 |
| Labor at steel mill, finishing to cars | 0.19 | 0.08 | 0.110 |
| Labor at receiving plant, cars to storage | 0.38 | 0.03 | 0.35 |
| Cost of bracing, including return freight on bracing materials by new method | 0.325 | 0.31 | 0.015 |
| Maintenance and depreciation, plant equipment of steel mill | 0.05 | 0.04 | 0.01 |
| Maintenance and depreciation, plant equipment of receiving plant | 0.04 | 0.03 | 0.01 |
| Freight-car damage | 0.416 | 0.00 | 0.416 |
| | $5.124 | $0.817 | $4.307 |

All direct costs are influenced by operating conditions. Figs. 2, 3, 6, and 7 of the Appendix contain theoretical curves showing the effect on the operating costs of different types of trucks resulting from variations in:

1 Length of haul
2 Amount of material to be handled
3 Condition of runways
4 Number and severity of ramps.

In addition to the above, the following conditions have a decided effect on the cost of operation. However, this case does not admit of any analytical treatment. Experience will have to be used in determining their influence in the choice of any type of equipment:

5 Width of runways and available space
6 Fragility of material handled
7 Special requirements in handling
8 Labor market conditions
9 Range of uses for which equipment is employed.

All or any one of the above factors may govern the selection of the most economical equipment but it is the authors' thought that the chances for a correct solution to the problem will be increased by a separate consideration of the component elements.

Geo. F. Swain, past-president of the A.S.C.E., has often been quoted as saying that a most common fault of the engineer is the carrying out of computations to a greater degree of accuracy than was warranted by the data from which these computations were made. Nowhere is this statement more applicable than in the field under our consideration, as the deciding factors in the purchase of materials-handling equipment are often those impossible to evaluate in dollars and cents. Such a statement should not be interpreted as implying that accurate cost figures are not valuable. They are, and when supplemented by a thorough investigation into all indirect savings, they form the only proper basis on which to make the final decision in questions of this kind.

Indirect savings effected by the introduction of a new system of handling or the purchase of new equipment are most readily taken care of by considering them as an indirect cost of the old system. If interest charges on the system under consideration be included in the cost and all savings are charged as costs of the system where they are *not* realized, the difference between total costs will then be the net yearly profit accruing from the change. If interest charges are omitted the difference in costs represent the annual savings which are available to meet the interest charges on the new system. An outline for computations of this kind is included in the Appendix.

Although difficult to evaluate, the following savings should be

considered so far as possible in figuring the net cost of operation of the electric industrial truck:

Fixed Charges:

1 Decrease in interest charges on manufacturing and storage facilities
2 Decrease in interest charges on inventories
3 Decrease in insurance charges on the two items above
4 Adaptability of system to growth in capacity.

Operating Charges:

5 Decrease in labor burden and managerial overhead
6 Decrease in idle hours of machines and workers
7 Decrease in charges for goods broken in process
8 Decrease in hazards to workmen
9 Decrease in expenditures due to labor turnover
10 Increase in general morale.

Offsetting these indirect savings we have the following indirect costs:

1 Interest on plant changes necessary[2]
2 Lost production during changes.

Decreases of insurance, goods broken in process, and hazards to workmen, as well as capacity for expansion, refer particularly to the installation of electric industrial trucks and tractors, the balance being applicable to mechanical systems regardless of type.

In summarizing the contents of the paper we find:

1 That in an effort to lower the cost of production, the mechanical handling of materials is coming into more and more prominence, but that variation of conditions makes comparative cost accounting difficult.
2 That a fairly simple classification of direct costs is possible.
3 That in average installations the electric truck costs in the neighborhood of 50 cents per hour to operate.
4 That in specific installations there is a considerable variation of cost.
5 That the influence of operating conditions is capable of being analyzed.
6 That indirect savings or costs are always present though difficult of valuation.

# Appendix

## THE COES FORMULA

As a typical example of a method of figuring investment justified or savings from operation we wish to refer here to the formula of H. V. Coes presented to the Society in November, 1923.

Let:

Debit Items:

$A$ = percentage allowance on investment
$B$ = percentage allowance to provide for insurance, taxes, etc.
$C$ = percentage allowance to provide for upkeep
$D$ = percentage allowance to provide for depreciation and obsolescence
$E$ = yearly cost of power, supplies, and other items which are consumed, total in dollars

Credit Items:

$S$ = yearly saving in direct cost of labor in dollars
$T$ = yearly saving in fixed charges, operating charges or burden, in dollars
$U$ = yearly saving or earning through increased production, in dollars

Results:

$X$ = percentage of year during which equipment will be employed
$I$ = initial cost of mechanical equipment
$Z$ = maximum investment in dollars justified by the above consideration
$Y$ = yearly cost to main mechanical equipment ready for operation
$V$ = yearly profit from operation of mechanical equipment.

Then

$$Z = \frac{(S + T + U - E)X}{A + B + C + D} \quad [1]$$

$$Y = I(A + B + C + D) \quad [2]$$

and

$$V = [(S + T + U - E)X] - Y \quad [3]$$

Feeling that handling machinery, even if left idle a large part of the year, would probably require, under most conditions, approximately the same repair through deterioration as though in use, the Committee makes no deduction for such lack of use in the estimated cost of upkeep $C$. If greater accuracy be considered necessary, use $C$ multiplied by $X$ in place of $C$ in the formulas.

In addition to the above items two other items may be considered. First, the interest earned on the depreciation reserve, which at 6 per cent is equal to 3 per cent on the value of the investment. This may be subtracted from item $A$ or $D$, the net being $A'$ or $D'$.

The second item is the interest on investments made in plant changes necessary before utilizing the mechanical equipment. This might be added as follows:

$F$ = yearly interest charges on cost of necessary changes to plant
$F = 0.06G$ ($G$ being the investment in plant changes)

This factor is added to the formula as it may play such an important part in the ultimate savings. One case is known where an investment of $1,500,000 was made in runways, bridges between buildings, etc.

Thus formulas [1], [2], and [3] above may be elaborated as follows:

$$Z = \frac{(S + T + U - E)X}{A' + B + CX + D} - G$$

$$Y = I(A' + B + C + D)$$

$$V = [(S + T + U - E)X] - (Y + F)$$

## HOURS OF USE VS. COST

The amount of time a piece of equipment is in service has a distinct influence on the cost of operation but not as great as many imagine. Many plant managers say that the high initial cost of electric trucks or tractors prohibits their use because the equipment would not be of service more than a few hours per day. Supposing a case where a gasoline or electric truck will replace 4 men at $3.50 per day and assuming (which is seldom true) that the men can be employed productively when not handling material we can draw the three curves shown in Fig. 1 of cost vs. days per year or hours per day employed.

## EFFECT OF VARIOUS FACTORS ON OPERATING COSTS

The following curves are presented not as accurate results of tests made nor are they true graphical representations of the formulas which follow them. They are presented as a suggested method of approach to the problem of selecting the most economical equipment operating under given conditions.

### Cost vs. Length of Haul

The first condition to be considered is the length of haul. Letting $Y$ = operating cost and $X$ = length of haul, and assuming that the cost is influenced by this one condition only, the following formula is suggested:

$$Y = A + \frac{B}{X} + C\frac{X}{r}$$

The authors have included three terms in the cost formula:

1 The fixed charges represented by $A$.

2 The cost of the equipment when idling, being a constant $B$ which represents the hourly cost of the truck when stopping for short periods, times the time idle which is inversely proportional to the length of haul. The second term may then be represented as $B/X$. For hand or electric trucks $B = 0$.

3 The third term is the cost of the machine when moving. This

[2] In one instance an expenditure of $1,500,000 for this item was found to be justifiable.

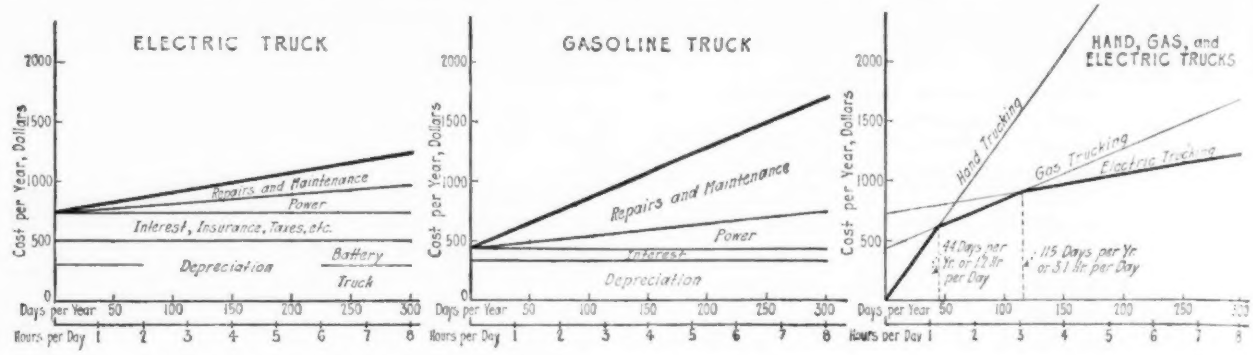

FIG. 1 OPERATING COSTS VS. HOURS IN SERVICE

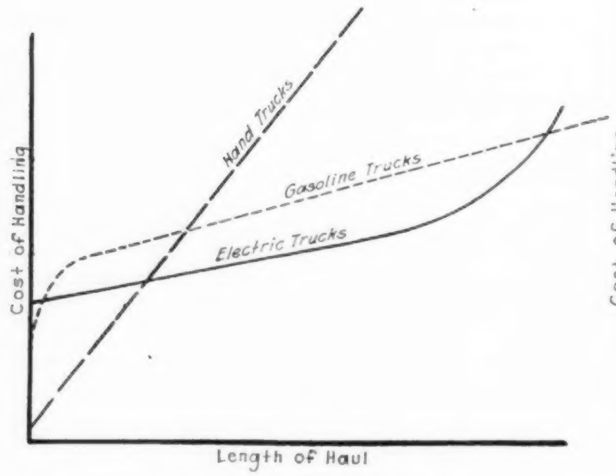

FIG. 2 COST VS. LENGTH OF HAUL

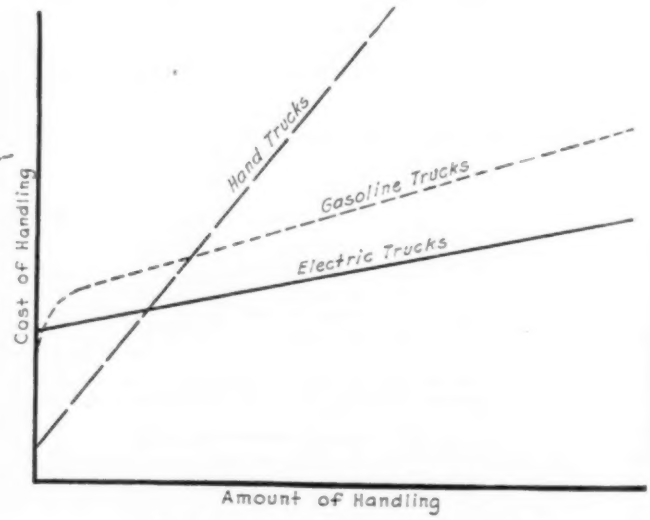

FIG. 3 COST VS. AMOUNT OF MATERIAL

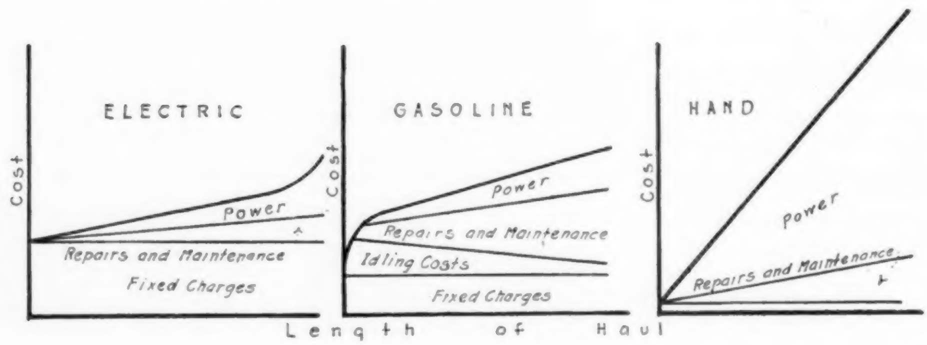

FIG. 4 ELEMENTS OF COST VS. LENGTH OF HAUL

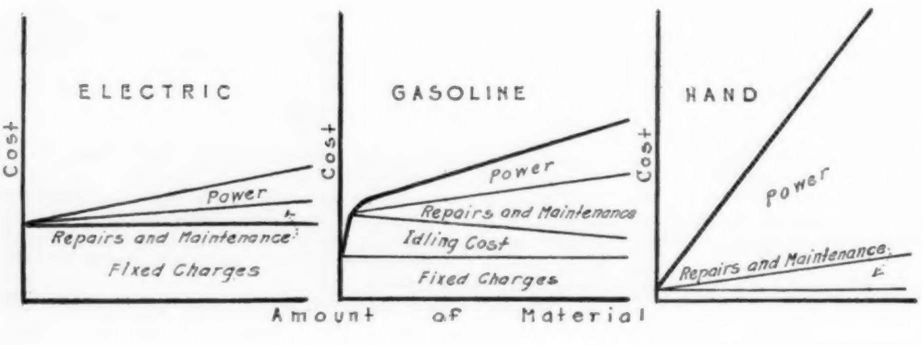

FIG. 5 ELEMENTS OF COST VS. AMOUNT OF MATERIAL

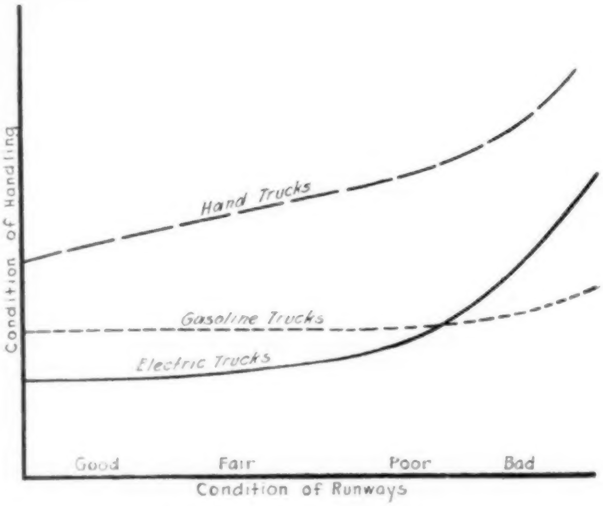

Fig. 6 Cost vs. Condition of Runways

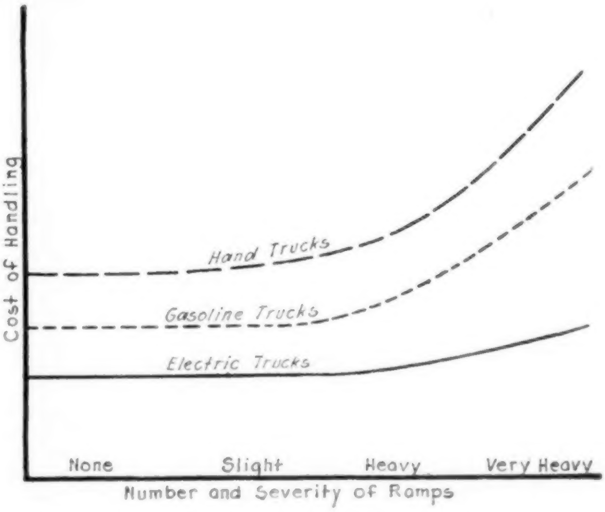

Fig. 7 Cost vs. Number and Severity of Ramps

term is a constant $C$ representing the cost per hour when running, corrected so that the variables remaining are only the length of haul $X$ and the speed of the truck $r$. The influence of speed is not seen in the cost until the hauls are of considerable cost.

The analysis of the different costs is shown in the curves of Fig. 4.

### Cost vs. Amount of Material

The second condition is the amount of material handled. The formula and curves are both similar to those for the length of haul.

The fixed charges are the same as before, the idling cost is proportional to the capacity of the truck and inversely proportional to the amount of material. The cost while running is proportional to the amount of material divided by the capacity of the truck. The formula is:

$$Y = A + B\frac{M}{X} + C\frac{X}{M}$$

where $B$ = idling constant
$M$ = capacity of truck
$X$ = amount of material.

The curves are shown in Figs. 3 and 5.

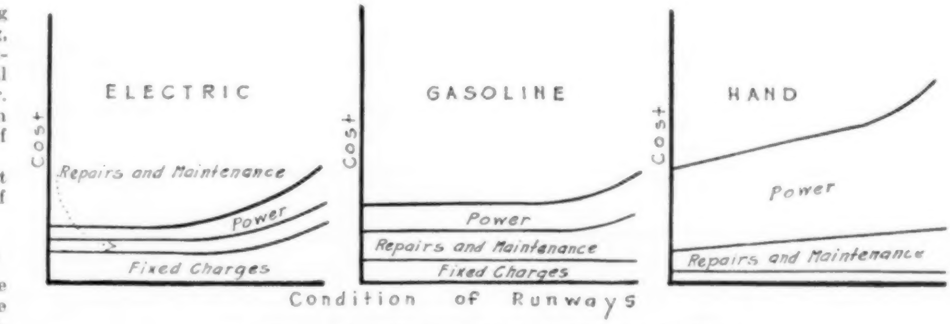

Fig. 8 Elements of Cost vs. Condition of Runways

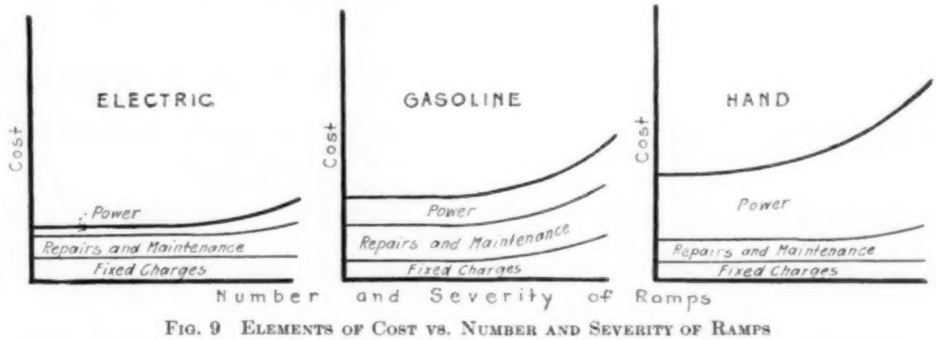

Fig. 9 Elements of Cost vs. Number and Severity of Ramps

### Cost vs. Condition of Runways

The third variable influencing cost is the condition of runways. The cost here is influenced by the amount of torque necessary at the hub and varies inversely with the size of the wheel. The electric has to retain the small wheel for the sake of ease in handling as the benefits therefrom generally exceed any trouble experienced on bad runways.

The curves are given in Figs. 6 and 8; the formula is as follows:

$$Y = A + B + C\frac{X}{DT}$$

where $D$ = diameter of wheel
$T$ = torque available
$B$ = constant for handling on smooth runways.
$X$ = coefficient for runway.

### Cost vs. Number and Severity of Ramps

The last external condition whose influence on cost is possible of any analysis is the number and severity of ramps. Considering as a base the fixed charges plus operating expenses on a level floor we may add a variable cost which is added by the ramps. This cost is principally one of power or more exactly one of overload capacity. As the storage battery has an overload capacity of 300 per cent or more the operating cost of electric trucks is little influenced by this item, being merely the extra power cost. In the case of gasoline or hand trucks, however, with a definite overload limit, either units of larger capacity (or smaller loads) or a sharp increase in maintenance and repairs and power will occur.

The curves are given in Figs. 7 and 9, and the formula is as follows:

$$Y = A + B\frac{X}{M}$$

where $A$ = fixed charges
$B$ = cost of operation on level runways
$M$ = capacity of truck for overload
$X$ = coefficient for number and severity of ramps.

SUMMARIZED DATA ON COSTS, SAV-

| No. | Industry | Plant | Operation | Working Conditions | Type Truck |
|---|---|---|---|---|---|
| 1 | Automobile | .................. | Millwright service | Narrow aisles, congested areas | 2-ton crane |
| 2 | Automobile | Reo Motor Car Co. | Carbonizing | Extreme heat, 2 shifts | Modified high lift with forks |
| 3 | Automobile | .................. | General handling | Generally smooth inside and outside | All types. Lift in capacities to 10 tons |
| 4 | Brick | Westfield Clay Products Co. | Handling from kilns to storage and shipping | Rough outside runways. Partly over ground | 2-ton standard elevating platform |
| 5 | Chemical Manufacture | Lehn & Fink Co. | Handling from cars to storage through process and to shipping | Smooth runways but heavy grades | 2-ton standard elevating platform |
| 6 | Electric Railway Repair Shop | Milwaukee Electric Railway and Light Co. | General machine-shop haulage | Concrete runways, small elevators | 2-ton standard high lift |
| 7 | Foundry | Erie Malleable Iron | Hauling sand, castings, molds, slag, etc. | Fair runways. Air filled with grit. Regular overloading | 2-ton standard low lift |
| 8 | Foundry | ....Mfg. Co. | Core handling | Concrete runways | Standard tractor |
| 9 | Iron and Steel | ....Can Co. | Tin-plate handling | Fair runways, varying grades | Special tin-plate jaw-clamp truck |
| 10 | Iron and Steel | Clinton Furnace | Charging blast furnace | Fair runways, 52 in. clearance for truck | 32-cu.-ft. side-dump built on straight platform truck |
| 11 | Iron and Steel | Detroit Steel Products Co. | Handling spring parts and springs through plant and to shipping | Fair runways. Grade 9 per cent, 34 ft. long to shipping level | Standard 3-ton elevating platform |
| 12 | Iron and Steel | Dilworth-Porter Co. | Handling tie plates from presses to shipping | Concrete floors | 4-wheel, 42-cell tractor |
| 13 | Iron and Steel | .................. | Handling crankshafts through forge plant | Fair runways but intense congestion grades. Hot loads | 3-ton elevating platform |
| 14 | Iron and Steel | .................. | Handling fender stock from machines through cooling to pickling and from finishing to shipping | Congested runways | 2-ton rated-capacity ram trucks |
| 15 | Iron and Steel | E. G. Budd Co. | Handling dies | Fair | High lift |
| 16 | Leather | .................. | Handling chemicals, hides, stretcher frames, etc. | Slippery wet runways. Narrow | Low-lift 2-ton standard |
| 17 | Paper | B. P. Co. | Handling rolls and flat stock | Concrete runways | 2-ton extra long platform, low lift |
| 18 | Paper | ....Lithograph Co. | Handling skid loads from cars to storage and to presses | Self-opening doors, concrete runways | 2-ton high-lift standard |
| 19 | Rubber | B. F. Goodrich Co. | Handling all materials throughout plant by skid and trailer loads | Underground tunnels, ramps, congested plant aisles | 2-ton high-lift trucks, standard tractors |
| 20 | Railroad and Marine | ....Terminal Co. | Handling freight from dock to car or warehouse | Rough—inside and outside | 2-ton high lift |

INGS, AND OPERATING CONDITIONS

| Auxiliaries | Hourly Operating Cost | Net Saving | Remarks |
|---|---|---|---|
| None | $0.45 | 30 men | This equipment is used for moving motors, machinery, etc. in order to take care of constantly shifting production layout. One in a fleet of 4 trucks. |
| Trestle for placing loads and chain hoist for dumping | | 6 men per shift | Approximately 50 per cent increase in effective furnace time has been obtained as the result of this innovation. Truck cares for 11 furnaces. |
| Skids | | $5 to $17 per car, net $4.83 | Skid shipment of materials to this plant from suppliers is beginning to be practiced. A further cut of 50 per cent is anticipated as a result of using higher capacity equipment. |
| 70 wooden skids per truck | | 6 men | This truck has solved the problem of labor in a district where it is scarce. It moves 35,000–40,000 brick a day in unit loads of 500 weighing about 2700 lb. |
| 100 wooden skids per truck. Hand lifts for short hauls | 0.53 | 19 men | Hand lift trucks are used for transfer of materials within departments, which cover relatively small areas. Roads are provided for practically all movements of the electrics. |
| 200 box skids per truck | | 5 men | Truck moves 100 loads in 8.6 hours. Many unusual jobs such as placing compressors under cars, handling stores in and out, etc. |
| Flat malleable skids: box skids and dump skids | | 4 men or more | Trucks are in some cases 12 years old. Minimum saving per unit cited. At this plant 4 pot-charging trucks handle 2500 tons daily at a total power cost of $4. |
| Special spring suspended trailer | | 62 man-hours per day | Breakage has been decreased and rehandling minimized. No difficulty experienced even in handling delicate cores. |
| Trailers for long hauls | 0.30 | $3.50 per car handled once | Impossible to cite net daily saving because load handled varies considerably. Equipment pronounced "eminently satisfactory." |
| 1 spare battery for each truck | | 4 men per shift | Trucks work 2 shifts. One truck handles 600 tons an average distance of 75 ft. every 24 hours. Better distribution in furnace claimed than by hand charging. |
| 250 all-steel skids for each truck | | 5 men per shift | One truck working on ramp and through plant, equipped with one spare battery, hauls 381 tons per day in 118 loads—an average load weight of 3.23 tons. Miles per day = 8.1. |
| 16 4-caster wheel 5-ton trailers | | 8 men per shift | At peak 665 tons are handled in 10 hours—a distance of from 50 to 150 ft. System is coordinated with overhead carrying equipment. Handling now involves no turnover. |
| All-steel skids | | 18 men per shift | Hot, heavy fast handling. Material in process kept on skids from time of shearing to shipment. 500 tons handled 5 to 10 times per day by 7 trucks. |
| None | | Cost earned once each month | Equipment has relieved congestion so severe that formerly periodic shutdowns of entire plant were unavoidable. Damage to product has been minimized. |
| None | | $112 per month | Saving is figured, by user, to include among other items the elimination of idle press time. Six-ton trucks are now used for this work in body-building plants. |
| Wooden skids | 0.60 | From 10 to 18 men | Equipment busy 8–12 hours a day. Hauls run to 1000 ft., outside. 2500–3000 lb. represents average load. Unusual reduction of labor turnover in sunning yard. |
| Wooden skids | 0.30 | 5 men | Materials are kept off floor throughout process. In some operations old hand trucks (4-wheel) carry loads which are pushed by power trucks. |
| Wooden skids 11 in. high | | 9 men | Power used nearly exclusively for moving material which is kept constantly off floor. Skid receipt of paper stock found to decrease unloading cost greatly. |
| None | Less than 0.40 | 6 men shift | Average load for truck = 1500 lb. Trailer load, 4500 lb. Average material moved daily by 47 lift trucks and 18 tractors between 9,000,000 and 9,500,000 tons. Average distance, 1787 ft. Total power charge on fleet per month amounts only to $175. |
| None | 0.43 | $6300 per year | Operation earning depends on length of time used. Operating cost verified by expert engineers. Saving cited a minimum. |

## Discussion

C. B. Cook.[3] The figures which the authors use appear to me to be quite conservative. In view of our experience, there seems to be an utter lack of records of costs in handling material by hand rather than machine. As a result we have nothing with which we can start. The costs which have been mentioned have been entered in overhead, whereas when one establishes a material-handling department it is usually put on its own basis, and these costs stand out as not before. It is therefore quite important that every encouragement be given industry to separate hand material-handling costs, first, to give them importance, second, for purposes of comparison with other means.

W. C. Brinton.[4] The paper brings out a thought I believe is important in the matter of large investments for the application of materials-handling machinery, such as electric trucks and tractors. Two or three years ago I asked for prices on the concrete paving of factory yards and was quoted a figure, roughly, of $10,000 per acre. One large foundry on a railroad system has about eight acres of yard where castings are stored, and for some three winters, electric lift trucks have gone over the whole area, which is nothing but cinder-fill. I believe it is usually possible to work in existing factory yards and between the buildings by using equipment that will suit the yards rather than spend $10,000 an acre for concreting them.

Take the subject of shipping. In the shipping of castor beans, for instance, one man by using a lift truck now saves the work of about twelve men. Heretofore the 150-lb. bags of beans were carried on the men's backs.

In handling brick at the New York City piers the brick must be stored near the pier. Lift trucks are doing this work, taking the brick about two city blocks away from the pier and putting it in a place under the open to be held until needed on the different construction jobs.

The accident-insurance rates have gone up recently to something like 12 or 15 per cent of the total paid to the longshoremen in loading and unloading ships. It is the duty of engineers to show the waterfront employers, superintendents, and managers how machine methods can reduce accidents.

Spencer Miller.[5] In handling material, it is the lift part that is difficult. Horizontal conveying is relatively simple. The great, successful industries that I knew forty years ago were those which had really solved their problems of material handling. One of the can factories of Chicago which later was a part of the American Can Co. made cans marvelously cheaply by improved apparatus, an essential part of which was the shop transportation system. The belt conveyor was a big factor in the making of the Duluth grain elevator, that great place for sorting wheat. And in the packing houses in Chicago the progress in material handling has been just as marvelous.

M. W. Potts.[6] With no other type of equipment than that for mechanical handling is it possible, when conditions change, to salvage so large an amount. A particular machine served by a lift truck may be taken out and yet one can find at least fifty per cent use for the lift truck with something else. This is also true of the conveyer. A year from now it may not be needed for the purpose it is now being used, but it can be put to some other use.

[6] Flushing, L. I., N. Y. Assoc-Mem. A.S.M.E.

J. C. Gillette.[7] One point of saving with the electric truck mentioned in this paper has come up in our plant, namely, the night delivery of materials with the electric truck. Practically all materials are delivered in the basement. We use chutes, the discharge of which are kept off the ground high enough to unload on to the skid without lifting.

We use 3-by-5-ft. skid bins for such materials as rosin, paraffin, asphalt, etc. At night our electric trucks deliver these materials to the department where they are to be used during the day. This produces quite a marked saving on elevators, congestion in the aisleways, and the interference with the workers. An electric truck cannot pass through a five-foot aisleway, close to the backs of people working on each side without their slowing up. It can, however, at night.

The electric truck has proved very valuable to us in the placing of portable equipment, such as fans, blowers, etc. We also place the electricians', pipefitters', and millwrights' emergency equipment and supplies on skids, and in case of a breakdown they can be quickly taken to the work.

Mr. Potts remarked about the flexibility of conveyor systems. We have a beautiful example of this with the exception of a few curves. Every foot of conveyor equipment we had in use last spring has been moved, rebuilt, and put back in service.

H. V. Coes.[8] I was particularly interested in the paper, and should like to see the supporting data brought out. If it is to be of real use to industry, we need the fundamental information from which these graphs are derived. Some of us may arrive at different conclusions, but if the supporting information is available, some one may find ways and means of using it to even a greater extent than has been presented here.

C. H. Bigelow.[9] It is important that trucks be made heavy and strong enough to stand hard usage, for the class of men that use them are not as careful as they might be. Another question to be considered is the unit cost of power.

Max Sklovsky.[10] The company with which I am connected has in seven of its plants, truck and tractor equipment for materials-handling purposes. Three other plants of the company have no such equipment. As a result, in the seven plants so equipped, we have very little in the way of difficult materials-handling problems. Such difficulties are in those plants where we have no such adequate equipment. We find it is more difficult to operate a plant without tractor equipment than with it. One example will illustrate this. In one plant where we formerly employed about 60 men for materials-handling work, we have now reduced the force to about 18 or 20 men. It is much simpler to acquire and utilize apparatus than it is to place men for such a class of work.

In one of the equipped plants we have ten electric tractors and five gas tractors. A year's operation on these shows an average of $840 for the electric tractors and $560 for the gas tractors. These results do not agree with the curves shown in the paper. However, the gasoline tractors in this instance have been in service about one and one-half years, while the average age of the electrics is approximately eleven years. As a result, the maintenance is higher on the electrics than on the gas equipment, so that it would modify the margin previously indicated.

[10] Chief Engineer, Deere & Co., Moline, Ill. Mem. A.S.M.E.

The question of investment is one that can be looked at from different standpoints. As a result of using various types of handling equipment, we have been able to reduce lost time and delays so that the factory output has been increased accordingly within the same areas and with the same production equipment. The cost of handling equipment is therefore more than offset by the reduction in outlay for building areas and added production machinery which would otherwise be needed. A further advantage accruing in part to proper handling equipment is that of control of inventories. Delays in handling tend to increase the intermediate inventories; that is, process inventories. By a sufficient systematic handling plan it is possible to hold such inventories within a much smaller range than otherwise. Handling equipment on this account helps in the effort to control factory inventories, and in one instance, as a result of various endeavors including systematic handling of materials, the inventories were reduced to a 12-day supply, whereas previously a 45-day supply was carried.

C. B. Crockett. One discusser mentioned a percentage return on the investment and the materials-handling equipment having to pay for itself in a year or two years. That is a great obstacle to overcome. A central-station company will buy generating or substation apparatus if it can earn 6 per cent on the investment, but if one tries to sell materials-handling equipment to a central-station storekeeper, he expects it to pay for itself at the rate of fifty to one hundred per cent a year.

Mr. Bigelow remarked about the question of power for trucks. Generally electric-truck equipment is charged at night, during what is known as "off-peak" hours, and if anything, the use of electric handling equipment improves the plant load factor, and in that way would decrease the unit rate at which the power is charged.

Any comparison of cost has a great many features in it: The age of equipment: are you comparing old equipment with new equipment? Have both types of equipment been in service long enough to be on an equal basis? Are they doing exactly the same type of work? Are any costs such as injuries to the workmen or breakdowns being prorated between the two, or charged up to each type of equipment?

H. J. Payne. I think that Mr. Coes has raised the question that is uppermost in all of your minds, namely, what right had we to take such liberties with these formulas. But, in connection with the work we have done, we say (the paper probably should have italicized it): "The following curves are presented not as accurate results of tests made nor are they true graphical representations of the formulas which follow them. They are presented as a suggested method of approach to the problem of selecting the most economical equipment operating under given conditions."

Mr. Crockett and I recognized that one of the greatest questions today in the use of materials-handling equipment is that of the power to put behind a motor truck. We have made studies covering two hundred plants. About twenty-five different types of gasoline and electric trucks are being used. There is something lacking in our data in the case of every study we have made. We have attempted to get all the facts available, and I think in a great many cases we have, but all the facts put together did not seem to us to justify making a curve and saying that it was the last word on the subject.

However, we do feel we have isolated four factors that underlie that proper choice of power to be used. As to Mr. Sklovsky's question in connection with these curves, Fig. 2 shows the cost vs. length of haul. Here we are forgetting there is anything to consider except the distance over which to move the material. We show that the hand-truck cost goes up rapidly. That is largely labor. The gasoline-truck curve starts to rise rapidly and then runs along at a uniform, moderate slope. The reason for that first curve is the fact that on very short hauls the gasoline equipment loses much time in starting, and on short hauls it spends a large proportion of the day in idling. On longer hauls there are not so many stops. Therefore, for the reason of very short hauls, the curve suggested for gasoline equipment rises rapidly.

With the electric truck, we show at the start a cost much higher than for the hand truck, because we are carrying higher fixed charges there, and then at a distance not defined but which we believe is in the neighborhood of 1000 ft. in many cases, the curve rises very rapidly, and later it is entirely out of proportion with the gasoline curve. I would assume that the reason for Mr. Sklovsky's views on both types of equipment is that he has found for certain types of work certain of these factors are important, and more or less force the use of one type of equipment.

# Materials Handling as an Aid to Production

By FRANK L. EIDMANN,[1] PRINCETON, N. J.

*The author surveys the materials-handling problem of a plant from eight angles: the design of building and arrangement of equipment, the weight of material handled per pound of finished product, the elimination of hand labor, the effect of the materials-handling methods on inventory, the effect on increased output of the worker, the design of the product to facilitate handling, the selection of the handling equipment, and attempts to facilitate handling in shipment and in customer's plant. Examples of good and bad practice are quoted, and illustrations of some are included.*

MATERIALS handling in the plant may be considered from many different angles, and it is safe to say that from whatever angle this problem is considered it stands out as one of the most important factors in influencing the costs of production and distribution.

With the ever-narrowing margin of profit in manufacturing, careful study is made of all the possible ways of reducing costs. It is natural that first attention is given to improvement of manufacturing processes and methods. As a result, development in these directions has reached a stage where it is now generally difficult to produce further spectacular savings, hence a broader analysis of all the factors which relate to production must be made in order to find other possibilities for reductions in costs. Savings in the cost of materials have received their share of attention, notably the salvaging of by-products and former wastes. Remaining for investigation, then, are those elements of cost which are usually classed as manufacturing overhead, and in segregating these it is found that the cost of handling the materials and tools in the plant is of greater importance than has been realized by the majority of executives. It has been truly stated that materials handling forms a large part of the so-called "hidden" costs of production, for there are very few firms which segregate and keep an accurate record of their handling costs.

In making a careful analysis of the materials-handling problem of a plant with the idea of attempting to make improvements, the chief motive is, of course, the ultimate reduction of the manufacturing costs. There are, however, a number of angles from which the survey can be made so as to bring out the possibilities:

1 From the viewpoint of the influence of the materials-handling problem on the design of the building and on the arrangement of the production equipment.

2 From the viewpoint of the total weight of material and equipment that must be handled to produce each pound of finished product.

3 The elimination of hand labor so far as possible.

4 The influence of the existing and the proposed methods of handling on the inventory, which includes a study of the methods which will make it possible to keep the material moving, so as to obviate the material's standing idle for lengthy periods between the various production operations.

5 To increase the output of each worker by delivering the material to him as fast as he can use it, and also to increase the size of the loads where consistent.

6 A study of the product from the viewpoint of designing it to facilitate its handling.

7 The selection of the proper handling equipment:

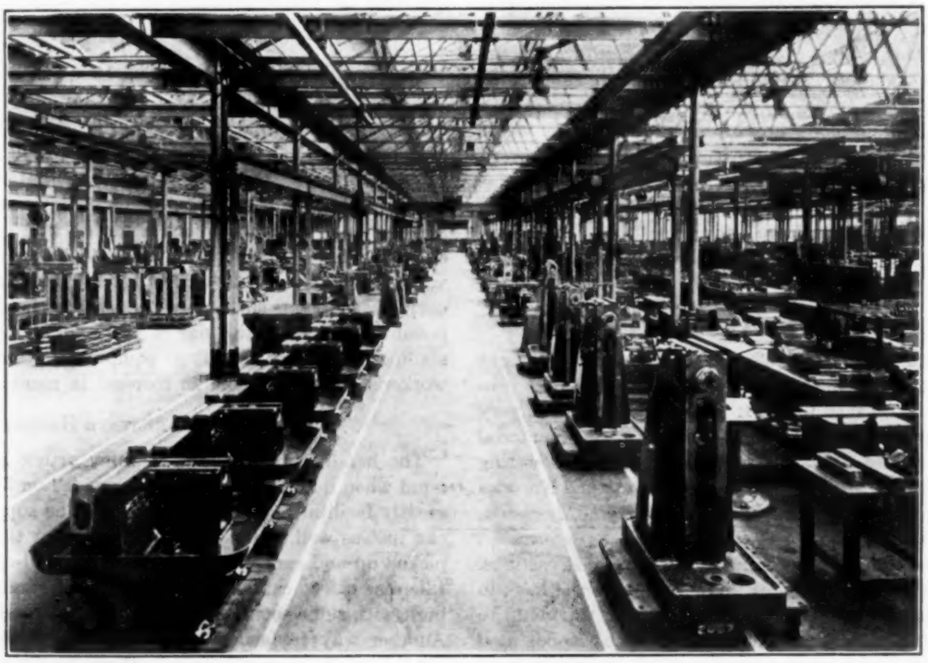

Fig. 1 The Cincinnati Milling Machine Company Handles Its Castings on Lift-Truck Skids from the Time They Are Received Until They Are Shipped as Completed Machines. The Assembly Floor Is Shown in This Photograph

[1] School of Engineering, Princeton University. Mem. A.S.M.E.

Contributed by the Materials Handling Division and presented at the Annual Meeting, New York, N. Y., Dec. 5 to 8, 1927, of The American Society of Mechanical Engineers.

*a* To provide economical handling of material from one place to another

*b* To provide safety for the operator of the equipment, as well as for other workers of the plant.

*c* To facilitate coordination of the handling equipment with the production equipment of the plant as well as with the handling methods in the other departments of the plant.

8 To facilitate shipment of the finished product to distant customers, and to facilitate handling in the customer's plant.

### Influence on Design of Plant

Referring to the influence of materials handling on the design of the plant building, it is interesting to note the change in procedure which has taken place in starting a new plant. Not many years ago, when a new plant was started it was customary first to construct the building, and after its completion the machinery was arranged to fit the structure. Later it became common practice to make a careful study of the desired machine arrangement before building the plant, and then to build the structure around this predetermined layout of equipment. The present method, however, is first to study the materials-handling problems, then to plan the proposed arrangement of equipment, and finally to design and construct the building to meet the requirements of both. This change is indicative of the growing recognition of the important part which materials handling plays as a factor in production.

Materials-handling methods are often an important factor in conserving floor space. There are many instances on record where the erection of new buildings has been rendered unnecessary through the adoption of improved methods of handling and storing materials. In a large gas-engine plant, after progressive assembly and a conveyor system were introduced, only about one-third of the floor space in the plant was required.

### Weight of Material

The second angle of investigation deals with the total weight of material and tools that has to be handled in the plant to produce each pound of finished product. This total weight is very high, and any improved methods of manufacturing or of material handling which reduce this will naturally result in lowering the cost of the product. In the foundry of the Blake and Knowles Works of the Worthington Pump and Machinery Corporation, for example, a careful analysis was made, and it was determined that 152 tons have to be handled for every ton of brass castings. For making one ton of iron castings, 206 tons of material have to be handled. These figures include the handling of the metal to and from the melting furnace, all handling of the materials used in core making, handling of sand equipment in molding, handling in the processes of cleaning and snagging, and delivery to the shipping room. Likewise, in the machine shop, or in any other plant, it is apparent that the total weight of materials and equipment that must be carried and lifted in order to produce a pound of finished goods also reaches a surprisingly high figure. A casting to be fabricated in the machine shop, for instance, has to be unloaded from the freight car or motor truck into the receiving room; usually it has to be lifted to be inspected; it has to be moved to the stock room or place of temporary storage; it has to be drawn from stock and then moved from machine to machine, from one operation to the next; it has to be lifted in and out of the machines; it has to be handled in the assembly and painting, testing, and preparation for shipment of the finished machine in which it is used; and finally it has to be loaded on the freight car. But that is not all, for many tools and pieces of equipment have to be handled, as well as quantities of supplies, to produce the part.

Naturally, the simplest way of cutting down the cost of materials handling is to eliminate manual handling as far as possible. If time studies are made in connection with making the investigation of the weight of materials that has to be handled to produce a single pound of product, one is again impressed with the shortness of the actual fabricating operations as compared with the total time involved. Some such time studies are reported which show as low as 10 to 15 per cent of the total time used in actual fabrication. The other 85 to 90 per cent of the time is used in handling the part, as well as tools, equipment, and supplies which are to be used on the part.

An analysis of time studies of this kind will sometimes suggest the elimination of some of the handling, and may further lead to the adoption of electrical or mechanical means of replacing manual handling.

### Influence on Inventory

Another angle from which materials handling affects costs is in its influence on the inventory of stock in process. If the material can be kept moving, without delays, from operation to operation, it is possible to run the plant on a much smaller inventory, which results in a reduction of invested capital and increases the yearly profits on account of the increased turnover of the materials.

### Delivering Material to Worker

The fifth study—to increase the output of each worker by delivering the material to him at the rate at which he can use it—goes hand in hand with the fourth, which has just been considered. In many plants there has been a substantial increase in the output as a result of the elimination of the waiting for materials. Where the product is of such a nature that conveyors may be employed for delivery of the material to the worker, the conveyor serves as a pace setter and usually shows an increase in the output. In plants such as dyeing establishments it is sometimes possible to increase the size of the loads to be handled by installing improved handling equipment, thus increasing the worker's output without an increase in manual effort required.

### Design to Facilitate Handling

The handling of a heavy or bulky article should be kept in mind when it is designed. Lugs provided on heavy castings will greatly facilitate handling by crane. The supports of machines can just as well as not be designed so that the machine can be picked up and carried by an electric or hand-operated lift truck. Likewise safes, cabinets, and articles of similar nature can be built with sufficient floor clearance to accommodate a lift truck. Another way to facilitate the handling of boxes, barrels, and other loads is to secure feet to them, to allow the proper floor clearance for the entrance of a lift truck. In similar manner the part may be designed to be handled by other types of equipment, greatly reducing the labor required.

### Selection of Handling Equipment

The selection of handling equipment is too far-reaching in its effects to be done haphazardly. It is not always a simple matter to decide which type of equipment is best suited to a handling problem, because sometimes it would appear as if any one of several types would serve equally well, whereas a thorough analysis of all the influencing factors by an expert who is not partial to any single class of equipment will usually show that one of the several available types will have definite advantages over the others for the particular problems at hand. Each type of handling equipment will be found to possess certain advantages for certain conditions, and there is no single type that will serve as a panacea for all handling problems—notwithstanding the ex-

tensive advertisements of some manufacturers of handling equipment. As previously stated, it is best to have the final selection of handling equipment made by an expert who is not partial to a single type of equipment. Some plants place such a man in charge of all materials handling, and in some of the larger plants the materials-handling department is well organized and the equipment is scheduled to jobs on a time-study basis and the operators are paid on a piece-rate or bonus basis. Smaller plants may not be able to afford the services of a materials-handling specialist. In that case it is suggested that a consulting specialist be called in occasionally to make a thorough and impartial analysis of the existing handling methods and to make suggestions. In most plants wasteful handling conditions are allowed to exist because it is no particular person's duty to correct them, and often those who know better allow such conditions to continue simply because they have existed for a long time and no especial thought has been given them. Not long ago the author visited the foundry of a well-known manufacturer and was surprised to find that whenever a mold had to be lifted or a core placed in a mold, the molder had to call four or five other molders from their work to help him. A hand-operated crane or a couple of jib cranes provided with chain hoists would have paid well for themselves. In another plant seven men were observed lifting heavy beams to the ceiling and holding them in place while other men secured them. If there were a materials-handling specialist in the plant he would undoubtedly have made use of the portable elevator, which was standing idle in the next department. One man, with the elevator, could have taken the place of the seven men referred to. In a third plant, which incidentally produces labor-saving machinery, about seven men were required to move the completed machines to the shipping room—and it was a long and laborious struggle. With hand lift trucks that were available in the same department of the plant, the machines could have been moved by two men in a fraction of the time, as is done in other plants of a similar nature.

One of the most essential requirements for a handling system is that it provides economical handling from one place to another. Sometimes, however, this requirement is secondary to other considerations. For instance, in one of the large tire factories at Akron it developed that the reason for installing a very extensive system of conveyors was not so that the handling from one place to another might be accomplished at lowest cost by this method, but because of the fact that work could be performed on the product while it was being moved. It was stated, in fact, that there were other available methods which would do the handling at lower cost.

### Safety

More important even than the consideration of handling cost is the provision of safety to the operator of the equipment and to the other workers of the plant. In general, any equipment which reduces the manual handling will greatly decrease the number of accidents. In this connection it is suggested that more firms establish the policy of providing critical inspection of all handling equipment and its use, from the viewpoint of safety. Insurance records show that a large percentage of injuries is due to falling objects—very often material falling from handling equipment. The Gleason Works and other firms find that it pays to place the responsibility for this inspection on a capable engineer. Special study is made of the proper way to arrange loads of material on the various types of equipment so as to eliminate the likelihood of accident. In the selection of equipment it is also well to look for attachments which make the equipment "foolproof." Consider, for instance, the electric industrial truck. It is now general practice to interconnect the brake and controller so that the danger of accident is greatly reduced. In order to operate the controller, the operator must hold the brake pedal in a depressed position against the action of a spring. Suppose the truck is running along at full speed and the operator for some reason becomes frightened, and jumps off the truck. The brake will automatically be thrown into action and simultaneously the electrical contact in the controller will be broken. Suppose the operator now returns to the truck and depresses the brake pedal while the controller handle is still in the running

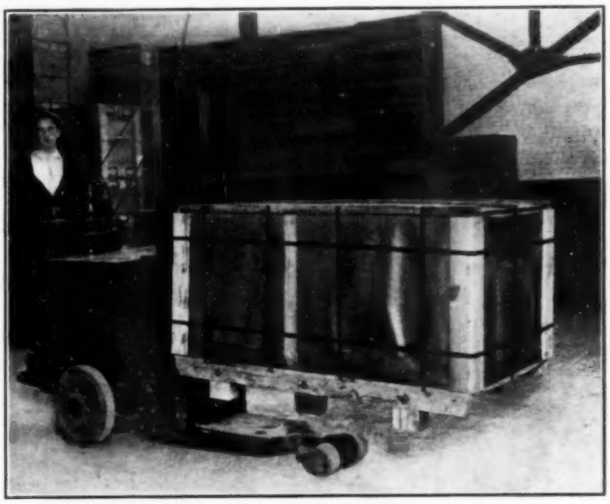

Fig. 2 The Practice of Shipping Product Loaded on Skids Is Rapidly Increasing. The Special Skid Illustrated Is One Which Has Been Developed by the Champion Coated Paper Company

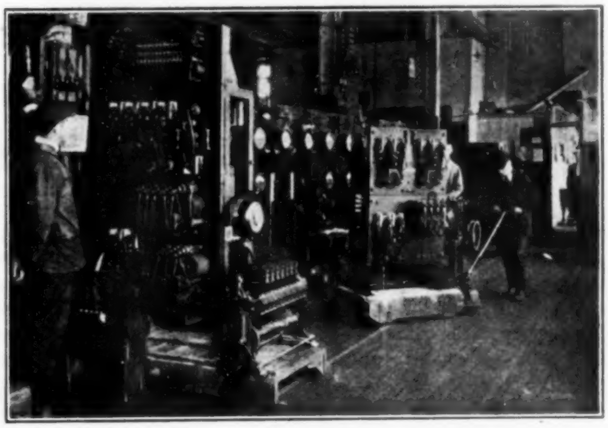

Fig. 3 At the Otis Elevator Company's Plant, the Control Boards Are Assembled and Handled Through the Test and Inspection While Secured to Lift-Truck Skids, Saving Considerable Manual Handling

position. The truck will not start. The controller handle must be returned to the neutral position before electrical contact will be made, and the machine has to pass through first and second speeds before it can be thrown into third.

### Coordination and Flexibility

Another point to consider in selecting handling equipment is the possibility of coordinating it with the other handling equipment of the plant as well as with the production equipment. There are plants where different types of handling equipment are employed in the various departments, with the result that there is considerable waste of labor in transferring the loads from one

department to another. Most types of handling equipment can be coordinated to use with other types. Usually some way can be devised of handling the same load by the different types of equipment without involving any manual handling in making the transfer. Flexibility is sometimes an important point to consider in selecting handling equipment—flexibility from the viewpoint of being able to employ the equipment in all parts of the plant, under low ceilings and balconies, on and off elevators, and in congested aisles. As previously stated, there are many

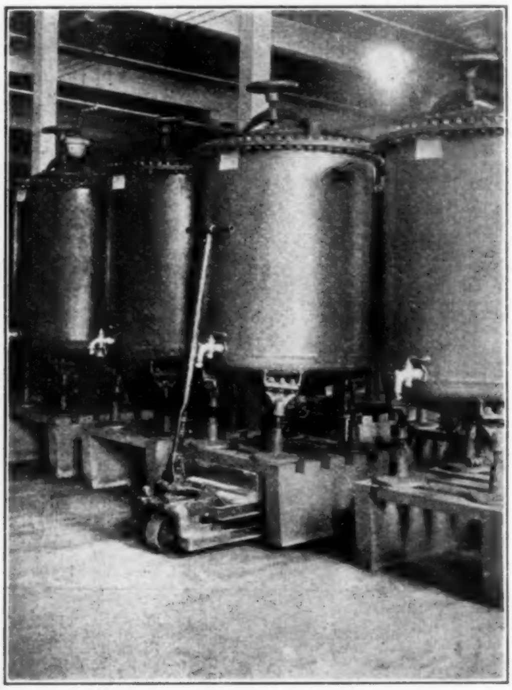

Fig. 4 The Handling of Heavy Loads May Be Greatly Simplified by Securing a Set of Feet or a Special Skid Thereto. This Photograph Shows How the United Drug Company Handled Its Heavy Vats of Perfumes

things to consider in making a selection, there being hardly any two installations which face exactly the same problems. Even the matter of fire-insurance rates is influenced by materials-handling methods. In a number of instances insurance rates have been lowered upon the introduction of the lift-truck and skid method of handling. The explanation for the rate reduction lies in the fact that this system allows for rapid removal of the stored product, thus decreasing the damage resulting from the operation of fire sprinklers. Also, the loads being at skid height above the floor, the liability of damage from the wet floors is reduced.

### Return on Investment

One of the important questions which is asked when the purchase of handling equipment is proposed, is, "How long will it require to pay for itself?" There is considerable divergence of policy among firms as to the answer to this question. Some firms require that the period be less than a year; others fix it at two years; while some are satisfied if the annual savings in production costs which result from the purchase can be shown to be greater than the annual charges against the equipment. One large company makes it a rule to require the new equipment to pay for itself, in labor saving alone, within a year. There may be additional large savings which result from the use of the equipment—such as in floor space, cutting down inventory, reduction of accidents, reduction of breakage of materials, and increased production—but the savings in labor alone has to pay for the equipment in the allotted time. Few firms keep accurate cost records of their materials handling, and it is therefore usually impossible to say exactly what savings have been accomplished through the adoption of a new piece of handling equipment, other than to state that the labor item has been reduced by a certain amount. Spectacular savings have resulted from the installation of each of the many types of handling equipment. In some plants new conveyor installations have returned annually as high as 100 per cent on the investment. In other plants the wages of a man were saved for each air hoist introduced in a particular department. Reports on many electric-truck installations show a saving of the wages of from three to five men for each truck employed. There are other reports of large savings resulting from the use of portable elevators—in one instance a saving of $2200 a day. Reports from many users of hand lift trucks indicate that each truck saves the wages of one man—about $1300 a year—not including the other savings mentioned in this paper.

### Shipping Methods

The last of the viewpoints from which the subject is considered is that of coordination of handling in the plant to the shipping methods. An example is the rapidly growing practice of shipping goods to distant plant on lift-truck skids. This method of shipping was first tried by the pulp manufacturers. The pulp was loaded into freight cars on lift-truck skids, saving considerable labor in loading the car and also in unloading and handling the pulp at the paper mills. This met with such success that the idea has been applied to the shipment of sheet paper—principally coated paper. The load is securely strapped to wooden skids, otherwise there would be likelihood of the paper sliding off the skid during transit. Some firms make up inexpensive wooden skids which are not returned to the shipper. Other plants are experimenting with a more permanent skid of which the cost warrants return for further use. This method of shipping has been extended to the shipment of sheet metal, which is loaded and strapped on skids similarly to paper. Products such as electric control boards and machinery are also being shipped on skids, and it is expected that this method will be extensively used within a few years, accomplishing enormous saving in time and labor of loading as well as a reduction of breakage. Some firms are now specifying that shipments come to them packed this way, and go so far as to send to shippers a set of printed instructions as to how to arrange the loaded skids in the freight cars so as to facilitate unloading, and also as to the dimensions of the skids to be used.

The importance of materials handling as a factor in production is unquestionably realized by management today, and considerable attention is being given to the improvement of existing conditions and methods; but only a beginning has really been made, and large opportunities for big reductions in costs still lie latent in this direction.

## Discussion

G. E. Hagemann.[2] Progress is rapid at present in the materials-handling field. The engineer is essentially the man who has the facts within his control and who is going to say how far this progress in materials handling shall continue? He is the only man who can keep in touch with new developments in equipment. It therefore devolves upon the Materials Handling Division more than on any other group to support the progress in that line of work and cut down the three billions or more of loss

[2] Associate Editor, *Manufacturing Industries*, New York, N. Y. Mem. A.S.M.E.

that industry is suffering annually because of inadequate and antiquated methods of handling material.

Materials handling today is far in advance of what it was ten years ago, and in the next ten years we shall certainty see a far more remarkable development. However, many plants will never buy handling equipment until the idea has been "sold" to them.

A small plant stands as much chance to save as the big one worth one hundred million dollars. We must remember, however, that we not only have to install the correct equipment, but also we have to make sure that we get the full use of it when it goes in. Further, a good deal of psychology must be employed in materials handling to get the workmen and supervisors to use the equipment properly. They can hardly be expected to do so all by themselves.

The Materials Handling Division of the Society has probably the biggest opportunity of any division for growth and development at the present time. We can point out how to save millions and millions of dollars a year that are now wasted in industry. The engineer should be a good lawyer to argue his case, a good salesman to sell the idea to the plant manager, a good economist to measure facts rightly, and a good cost accountant to state the financial facts logically and convincingly. If he can do this, there is no end to the amount of money that can be saved.

There is no plant in the country today that cannot next year reap anywhere from a ten to one hundred per cent bigger return on its investment in handling equipment through restudying its problems and bringing its methods and equipment up to date.

A. L. Lewis.[3] Because the writer is a manufacturer of lift trucks, stackers, platforms for lift trucks, barrel racks, and special designs of caster trucks, he believes his most worth-while contribution to the discussion will be to tell of concrete cases in ten major groups of industry where his concern's products have been installed and the savings effected.

1 *Chemicals, Paint, Varnish, Etc.* Company uses a lift truck for handling tote boxes 36 in. high and 36 in. wide which are inserted under a hopper and filled with a finely powdered chemical. The hydraulic-jack mechanism of the lift truck in question is such that the truck frame can be elevated and yet stopped at the right height to make the top of the tote box and the bottom of the hopper a pressed fit, which is necessary to prevent the material from filling the air.

2 *Food Products.* A branch of a well-known packing house uses lift trucks for handling crates of eggs. One man trucks from the freight car to the elevator and another on the lower floor from the elevator to storage. The time now is 40 working minutes. The previous time was 240 working minutes. When unloading cars of produce, two men pile it on platforms and another with the lift truck hauls it into the plant. Another concern stacks barrels of fruit three high in its cold-storage room, and the saving in floor space and labor thus effected more than paid for the stacker used in a very short time.

3 *Iron and Steel Products.* One concern uses hand lift trucks on each floor to take loaded platforms off the elevator. Later these loads are distributed where required by electric lift trucks. This method has increased the tonnage handled by the electric lift trucks very considerably, and is illustrative of how an inexpensive unit like a hand lift truck can increase the earning power of an expensive unit like the electric lift truck.

Another concern, which originally bought a stacker for piling filled boxes of rivets in storage, wrote that the machine had practically paid for itself during the equipment of its new building, because of the labor it had saved in hanging motors and shafting.

4 *Leather Products.* About a thousand hides can be stored on a platform, whereas not over 200 can be stored on the wooden horse that it has been the custom to use. The saving in floor space is consequently considerable, and one company states that the saving made by using three hand lifts amounts to over $10,000 a year.

5 *Lumber.* One concern unloads veneered panels used in the manufacture of kitchen cabinets by placing a wooden platform at the freight-car door and piling panels upon it. The platform is then raised off the car floor by a stacker and hauled away to the storehouse. Two men less are required on the job.

A manufacturer of casters uses hand lift trucks to handle the lignum-vitae, of which the casters are made, and which comes to them in four-foot logs, about 6 in. in diameter. Rack platforms were built and the logs are dropped from the railroad car to the racks. The wood is so heavy that a 4-ft-high load is all a man can haul. The trucks handle these racks and make a one-man job of what formerly was accomplished with difficulty by two men.

6 *Paper and Printing.* A large metropolitan newspaper is using hand lift trucks in the color-press department where the magazines and comic sections are printed. These sections are printed about a week in advance, and as they come off the presses are tied in bundles and placed on platforms 32 in. wide by 36 in. long where they are stored until made a part of the regular editions. The trucks and platforms save at least two handlings and materially speed the deliveries.

A paper mill uses a stacker for piling rolls of paper and boxes of paper to a height of 12 ft. in the storeroom. The rolls are trucked along the floor with an ordinary two-wheel hand truck, and dumped on to the elevating platform of the stacker. In this way the work is done with half as many men and half the time formerly required.

7 *Rubber.* A rubber company uses hand lifts for handling box-carton material. This comes into the storeroom by chutes and is piled on platforms and then moved by hand lifts to the storage space. When needed for printing the right sizes are picked out by platform loads and taken up to the press room. As the sheets of box board come off the press, they are placed on platforms and moved by hand lifts to the fastening machine which secures the sides and ends together. The lifts and platforms have been found superior to a conveyor.

8 *Stone, Clay, and Glass Products.* One concern uses a stacker for piling bath tubs four high instead of standing them on end as formerly. More than double the number of bath tubs are now stored on the same floor space, and this has paid for the stacker many times over.

A pottery company uses 10 hand lifts in two of their processes as follows: (1) After the pottery ware is sanded in the green room, it is put on boards about 6 ft. long and then placed on peg racks mounted on platforms. There are about 12 boards to a rack. The kiln man then takes it to the kiln. Then the ware is taken from the boards and placed in saggers (clay receptacles or crucibles). The ware is then put in the bisque kiln which finishes this operation. (2) After the ware is dipped and glazed it is put through the drier, placed on boards, and then 16 boards are put on each rack. The truck then takes the loaded rack to the gloss kiln. The old method was to have a man take one board at a time to the gloss kiln after the dipping. The men are on piece work but the management figures that the lifts still make money for them by increasing the amount of pieces produced each day.

9 *Textiles.* One dye works uses a stacker to hoist rolls of cloth up to shelves. Each roll weighs about 150 lb. Formerly these were piled only two tiers high. Now the highest is about 9 ft. from the floor, more than doubling the storage space available, which alone would be a big item. Further, four men were

[3] President, Lewis-Shepard Company, Watertown, Mass.

formerly required to do the work that is now done by two men, and by one at times.

In another dye house hot dyestuff in metal barrels is moved about on platforms by one man. Previously two were required to move these barrels, and they were occasionally scalded by hot dye slopping over.

10 *Warehousing and Distribution.* In one cold-storage building when fruit arrives by freight car, steel-leg platforms taken into the car and loaded, are hauled on hand lifts to the elevator, hoisted to the next floor, and then carried into the cold-storage room. Here a stacker picks up the loaded platform and hoists the load to a shelf where it is unloaded. The fruit has only been handled once. Three men now do what formerly required six.

An ice and cold-storage company uses lift trucks in the place of ordinary four-wheel trucks in handling crates, baskets, barrels, etc., that arrive at its warehouse by truck, wagons, and freight cars. Here the platforms and lift trucks are not used to save rehandling, and yet pay. It formerly cost about $100 per year for new casters on ordinary four-wheel trucks, and the lifts and platforms save this expense as well as speed up the unloading of automobiles, wagons, and freight cars, as they keep on hand a lot of platforms and the men are not idle waiting for ordinary four-wheel trucks to be unloaded and return again to be loaded.

The next two or three years will demand efficiency in management. There is no greater opportunity, the writer believes, to effect savings than by reduction in the present cost of handling materials.

M. W. Potts.[4] The author mentions safety. Material-handling equipment greatly increases the safety factor in a plant. It eliminates the accident hazard. Engineers should vigorously oppose the idea that material-handling equipment has to pay for itself in six months or a year. No other piece of equipment is bought on that basis. It is true in most cases, but it should be allowed two years or even more to pay for itself.

Six years ago the speaker recommended a certain installation of material-handling equipment in a plant in which he was working. The other day he had the pleasure of quoting them prices on equipment amounting to $13,000. The company has been losing $8000 a year for six years—$48,000 in all, which would have paid for the equipment two or three times.

W. C. Steubing.[5] When American industries first adopted the lift-truck system for their production departments and found that they saved up to 90 per cent of their former costs of handling, they extended its use to shipping on skids. They reasoned that if such great economies could be accomplished for inside transportation it could be tied up effectively with outside transportation. The principle involved was the elimination of unnecessary loading and unloading or rehandling.

Outside transportation, which included handling of materials at terminals, has been very costly. For example, the New York Central Railroad as a water-level route reported that it cost the road 74 cents to move a ton 250 miles, 75 cents to handle that same ton in loading on to the cars, and 75 cents to unload it—two-thirds of the cost being involved in the handling of the materials and only one-third in the actual transportation thereof.

The paper mills were the first to recognize the savings that could be effected for the consumer by tying up the lift-truck system with outside transportation. The Champion Coated Paper Company, of Hamilton, Ohio, inaugurated the idea for the shipping of their paper on skids. At first they used a substantial skid or platform that was to be returned to them, and invoiced it to the consignee on memorandum account at $25 per skid. Later they shipped their paper on nailed wood skids, with the load wrapped and strapped to the platform. The skid was made the exact size of the sheets, for better protection and closer packing in the cars. Formerly a case cost the company $4. The nailed wood skid cost them $2.50, but they could stack two and one-half times the load of a case on a skid, the relative cost of cases therefore being $10 as compared to a skid at $2.50.

But the greatest saving resulted through quick handling, it requiring but 40 per cent of the time to load a car with paper on skids as compared to loading in cases. Furthermore, it was possible to get the maximum weight in a car, reducing the freight, and as large sums were saved by the company in loading their material in this manner, it was in many cases able to reduce the price of its paper from one-fourth to one-half cent per pound to the consumer—aside from the economies the consumer effected by quick unloading of cars. The nailed wood skid was but a temporary unit for quick shipment, and was eventually replaced by the paper consumer with a more substantial skid. Various mills now ship their paper on skids to warehouses and consumers in various parts of the country.

Sugar is now being shipped on skids from Cuba to Atlantic seaports, but in this case a substantial platform is used so that the skids can be lifted into the hold of the ship. At the docks and warehouses the loaded skids are handled by heavy-duty lift trucks, and from there distributed to consumers.

The Great Lakes Navigation Company is effecting an enormous saving by handling of commodities that will pack closely on skids. The steamship companies recognize that their greatest cost arises where a ship is unnecessarily tied up in harbor for two or three days, and that their greatest gains come in actual transportation.

As a result of manufacturers' shipping products on skids, the railroads, which have always been slow to adopt the more modern methods applied in industry, have now accepted the application for their own use at several points. As an illustration: the C. M. & St. P. Ry. Purchases and Stores Division are loading their cars with supplies and equipment mounted on skids. Results show that for the coming year they will ship a tonnage to their various shops, terminals, etc., in 35,000 to 50,000 cars as compared to 77,000 cars during the past years. The minimum saving of 27,000 cars per year will effect such enormous economies as to make the cost of the lift-truck system insignificant. Furthermore, their savings on man power for loading and unloading will amount to 60 per cent of their former costs. They have adopted a standard skid that can be handled by electric lift trucks or hand lift trucks—the electric lift trucks being used at the main depot for the long hauls and the hand lift trucks for the short hauls. The hand lift trucks will also be used at the smaller shops or stations where there would be insufficient moving to justify the electric units. Their aim is to systematize their whole road with this method of handling.

The lift truck is a trackless crane, able to handle crane loads to any part of a building or outside, wherever there is a roadway to sustain that load. The orderly method of having loads mounted on skids, available for quick movement, has permitted in many cases the loading of cars within one day where otherwise it required two or three days. The method provides for quicker turnover of inventory with a smaller investment in stock, consequently greater profit.

One of its outstanding qualities is that it has proved to be one of the safest methods for handling tonnage, eliminating injury to operators, and preventing big losses in the handling of goods which has been damaged through other methods. Witness the shipping of sheet metal to automobile-body plants. These sheets must be free from blemish and are carefully inspected.

[4] Flushing, L. I., N. Y. Assoc-Mem. A.S.M.E.

[5] President, Steubing Cowan Co., Cincinnati, Ohio.

Through the lift-truck system the sheets are inspected at the time they leave the machines in the mill and placed upon a platform and then moved to a car and lowered away on intermediate supports to permit hand lift trucks to take the load and move it to the end of the car and place it across 4 by 4-in. stringers. Formerly the inspection took place in the car and each sheet was handled separately. With the lift-truck system the loads are placed close together and properly braced with 2 by 4's. The method permits cars to be loaded with from 80,000 to 110,000 lb., securing the lowest possible freight rate and safety in handling. One large automobile plant reported that with the lift-truck system they are now able to unload a car of sheets in forty minutes that formerly required seven hours.

It is apparent that this system will be applied extensively in the coming year. Special lift-truck equipment is being produced by certain manufacturers which specifically solves these problems and reduces the handling of materials from 60 to 90 per cent over former methods.

William F. Hunt.[6] It seems to me that the paper brings to the foreground the very important fact that the cost of handling material is an item in unit costs which needs and should receive increasing attention from the factory manager. I should like to suggest that the author consider the advisability of emphasizing in his paper another item, possibly under the paragraph, "Delivering Material to Worker," that factor being that of the convenience of receipt and dispatch affected by the location and the ease of transfer to and from the particular manufacturing operation for which the material is brought to the workman.

Frank G. Raymant.[7] The elimination of hand labor is receiving ever-increasing attention in Canadian industry. With few exceptions production in this country has not yet reached the stage of progressive manufacture and assembly, but correct materials-handling methods as applied to the handling of bulk materials are resulting in unlooked-for savings. This is especially true where bundles made up of many small pieces are received. The writer can recall the recent case of a company manufacturing steel springs where, in unloading flat bar stock alone, the installation of two electric cranes and a twin-hook hoist result in a saving of approximately $350 per month. With the increase in capacity of the plant thus made possible, prospective business indicates that the saving will shortly be well over $500 per month. The improved method eliminates the services of over three men. One hundred dollars per shipment formerly allowed for demurrage is an added saving due to the rapidity with which the cars can be unloaded. With the same floor space, storage is increased threefold, and by adopting an improved system of tagging and having the steel shipped in bundles which are left intact until taken to the machines, inventory is greatly facilitated. A saving equal to unloading is presented in feeding the machines from storage.

A similar problem in the handling of large quantities of lumber was recently solved by the installation of an electric gantry crane in conjunction with an electric transfer crane which feeds the numerous bays of the storage yard. Previously each stick of lumber was handled individually five times between the cars and shop, two men being required for each operation. With the new system the lumber is piled in standard-size piles on the wagons and further manual handling is eliminated by the electric crane. The crane is used to feed the dry kilns and the three floors of the shop. Storage per square foot is greatly increased and inventory is comparatively simple.

Many similar cases exist where manual labor has been reduced to a minimum or entirely eliminated. Unfortunately instances still remain where a proper diagnosis of present handling conditions and the application of proper equipment would mean yearly savings of many times the value of the investment. Another point worthy of mention is the satisfactory results to be obtained where the source of supply and the purchaser agree upon shipping material in standard-size bundles which facilitate handling and are a source of profit to all parties concerned. As the executive becomes more familiar with the indirect as well as the direct savings with which it is possible to increase his profits by increasing the efficiency of his materials handling, he will take a greater interest and activity to this end.

Merritt Lum.[8] One point I should like to emphasize is the making sure on our part of such standardization of heights, and such possible standardization of widths of platforms as will make it possible for the machine designer to design his machine to fit the material-handling equipment as he finds it today, or as it may become improved tomorrow.

A second point is the effect of the leaders in the use of material-handling equipment upon those users who are less progressive. The author might have carried farther his point of shipment on platforms by referring to certain industries and certain progressive firms where the buyers are specifying the manner by which the material must be shipped. I am thinking of such companies as the Hudson Motor Company, which, I understand, specify that material coming to them must come on skid platforms, and packed in cars in a certain way so that they may find it most convenient and economical to handle when it comes to them.

A third point is the simplicity of cost figuring. Wherever we devise a method of figuring costs of material handling we must realize that method must fit the purpose of the manufacturer or the factory superintendent or the manager as well as the engineer. Unless we get our formulas simple and put them in terms that are quickly grasped by the man who is going to buy the material, then we confuse rather than help the situation.

A fourth point is the recognition of material handling as a special function of an industrial plant, which should be in the hands of some man who is wholly responsible or at least has a major responsibility for such work.

A final point is the getting together of manufacturers, and their agreeing on the limitations and proper fields of application of the various types of equipment. Unless we begin to develop a mutuality of interest among manufacturers, then the buyer will continue to be confused and disappointed when, after purchase, he find he has been oversold on a type of equipment, whereas another type could do the work much better. That situation reacts on all types of equipment, and the Materials Handling Division has a grave responsibility in the matter.

J. C. Gillette.[9] In the Edgewater plant of our company which we have rebuilt and increased in capacity about 300 per cent, with the exception of moving from the basement to the fourth floor, practically none of our material moves without being worked on. We have something like a mile and a half of conveyors, practically all roll-way conveyors. Our work progresses through the plant with the belt speeds close to 25 to 30 ft. per min. with a piece of work on every foot of the belt, in some cases four abreast. Operations are performed on each

piece of work in practically every case just as close as the operators can stand conveniently.

Ours is practically a new problem, but comparing it with the old problem of making the 6-in. dry cell, the labor and handling cost is something around one-fifth of what it would have been under the old tray and truck method. I believe that one of the points that should have been included in the paper is "Fabrication of Materials in Progress," making nine points instead of eight.

H. V. Coes.[10] I wish that the author had brought out another subject that goes hand in hand and is practically a product of material handling. Material handling is more than just purely the question of handling material—if properly set up and coordinated it automatically schedules production. The great automobile plants in Detroit do not have complicated schedule boards or anything of that kind. If the material does not show up at a certain place, it stares one in the face somewhere else. They do not need any record or clerks to refer to. The situation is right there in front of them.

It seems to be characteristic of human nature never to arrive at a simple solution at the start. We ought to direct our thinking toward getting things less complicated and reducing our repair bills and maintenance charges. Much of the equipment sold is not designed apparently to stand the hard usage it will naturally receive, and the maintenance charges in consequence are high.

I should like to direct the attention of the Materials Handling Division to that phase of our work and to bring out concrete examples whereby any number of dissimilar units may be coordinated in material handling. In our plant we are using overhead cranes, electric trucks, gravity conveyors, roller conveyors, and they are operated as one system.

We should have available more data on maintenance charges of material-handling equipment. Then we could aid those who design and manufacture equipment by bringing back to them what our experience has been in the actual, everyday use of the equipment.

Next comes the question, "How can we still further utilize material-handling equipment to automatically schedule production?"

Charles H. Bigelow.[11] The economics of handling should be considered, because a given apparatus may be too expensive for the work to be done or the savings to be made. Another point is the geographical layout: What might be good for one place might be entirely unsatisfactory in another location. In coal handling, for example, where the coal is delivered above, it can be dropped by gravity to the boiler room. If, however, it is delivered below the boiler room it is necessary to elevate it.

A question came up about handling steel to the shears. The steel comes on open flat cars, in heavy bundles. A locomotive crane lifts the steel up and places it in piles, from which it is taken by the crane to the shears as needed. The idea was to have a conveyor run along the end of the piles and carry the bars up, but the question arose as to how to get the bars turned around and placed on the conveyor, and the best way seemed to be to use the crane to lift and turn the steel around, and then the crane might as well run two or three hundred feet further and drop the steel into the shears. We did not put that system in, although it looked very nice on paper.

In our plant, at present, we are using roller conveyors to slide the material from one machine to another in the shops. We are using a portable conveyor for loading heavy scrap. We shovel it on. The first car we loaded cost us about 33 cents a ton because the material kept rolling back down the conveyor, requiring rehandling. By reducing the speed we found we could load the material into the car at 24 cents a ton. Although the conveyor ran slower it was impossible to overload it, and the material did not have to be rehandled.

D. R. Long.[12] One speaker mentioned the matter of coöperating with manufacturers in using suitable containers to facilitate materials handling. In two instances by doing that our plant saved some money. We make paper tubes, rolling linoleum on them, and use about three and a half carloads of paper a week. In the center of the roll a couple of inches of paper were wasted, and on the outside, three or four layers were torn. So we started to use steel cores and steel bands on the edges of the outside of the rolls, thus cutting the loss from 10 per cent to $2^1/_2$ per cent in handling.

We use considerable rosin which is shipped from Georgia in barrels. We used to pay for the barrels, for the freight, and in addition for gross weight. The loss was high because the rosin sticks to the barrel, and the staves are very difficult to burn without smoke.

We cooperated with a manufacturer of tank cars, and he furnished us with one to experiment with. Now we are using tank cars entirely. The railroad pays us a cent and a half a mile for the tank cars, and we pay the usual freight rates for rosin. The savings we have made are the price of the barrel, the rosin that sticks to the wood, and the trouble of disposing of the wooden barrels.

Very often standard parts of material-handling equipment can be used to manufacture a special handling device. To illustrate, we needed a special low-head crane, lower than any manufactured at that time, and sent out specifications to four manfacturers of cranes. One of them sent a representative to our plant to see if the specifications could be changed. He learned that this was impossible, but in going through the plant he saw a piece of equipment he had furnished. This gave him an idea, and with it and some extra parts he made a special crane. Each part used was a standard piece of equipment, but assembled in just a little different way.

K. D. Hamilton.[13] Shoes today are being fabricated in the process of transportation, and I believe in ten years many shoes will be made on conveyors as automobiles are made, with the exception of high-grade shoes and extreme styles.

We recently installed a coal conveyor, and cut the cost of handling from a dollar down to six cents a ton. We were interested in ash disposal and found that contractors will pay good money for cinders. Instead of putting them in the dump we are now making a net saving of $600 a year on the disposal of cinders.

We use sixty Hudson cars for the transportation of salesmen, electric trucks in the plant, and lift trucks for conveying sole leather; we have 600 ft. of conveyor in the cutting department where small patterns are cut.

This old industry, with customs of fifty years ago, is modernizing, and will prove to be a very fertile field for conveyor installation in the next four or five years.

The Author. A number of points which deserve emphasis have been brought out in the discussion. To the eight view-

[10] Vice-President and General Manager, Belden Mfg. Co., Chicago, Ill. Vice-President A.S.M.E.

[12] Chief Engineer, Armstrong Cork Co., Lancaster, Pa. Mem. A.S.M.E.

[13] Mechanical Engineer, Walk-Over Shoe Company, Brockton, Mass. Mem. A.S.M.E.

points from which I considered the materials-handling problem in my paper, a ninth, as suggested by Mr. Coes, could well be added. It is "the influence of materials handling on the scheduling of production." Materials-handling methods where properly planned, coordinated, and supervised will help considerably toward the automatic scheduling of production, thus greatly reducing the expense of operating the planning department.

I am pleased that Mr. Lum referred to the fact that the field for each type of handling equipment is limited. Too often equipment is recommended and installed on jobs that could be more efficiently handled by another type of equipment.

It is also well to bear in mind that the materials-handling problem is important in the small plant as well as in the large one. The size of the plant may have an important bearing on the type of equipment to be selected. In the case of the smaller plant which is expected to expand, the handling system should be such that it can be expanded conveniently as required, without discarding any of the old equipment and at reasonable cost.

The author is in full accord with Mr. Hagemann in his statement that the goal has not necessarily been reached when the correct handling equipment has been installed. It is quite as important that the equipment be properly used and that full use be made of it. The author has seen many instances where the equipment was incorrectly used, greatly lowering its usefulness, and he has found many cases where the equipment was used to only a fraction of its full usefulness.

The specific savings mentioned by Messrs. Hamilton, Raymant, and Steubing as being accomplished in certain instances due to the improvement of materials-handling equipment or methods are typical of what can be done, and it is not surprising that materials handling is now being recognized as an important aid to production and a factor in which great possibilities exist for the reduction of production costs.

# Cargo Cranes—Types Available, Factors Governing Selection, and Latest Developments

By BERNARD DUNELL,[1] VANCOUVER, B. C.

*In this paper the author discusses the several types of cranes used on docks for removing cargoes from ships and placing the articles handled, that is, crates, barrels, bundles, etc., at the points desired. Two general types of cargoes must be handled: namely, bulk cargo and general cargo. The disadvantages of some of the common types are mentioned, and the manner in which these have been eliminated in later designs are pointed out. The types of loads best handled by different types of equipment are mentioned, and recommendations as to proper equipment are made. It is shown that, while in some cases as high as 50 tons must be lifted, the most popular general-cargo crane is of from three to five tons' capacity. The author emphasizes the importance of proper attention to dock conditions in the determination of wheel loads, and therefore, the crane capacity, in the case of existing docks, and where new construction is contemplated the desirability of adequate strength to take care of the maximum load likely to be imposed. The hoisting rope receives considerable attention in the paper. The disadvantages of the two-strand fall are pointed out, and it is recommended that it be avoided wherever possible. A disadvantage of the ordinary luffing crane is that when the jib is luffed in the load suspended from the jib head is simultaneously raised, resulting in wasted work and requiring a more powerful motor than otherwise would be necessary. Level-luffing cranes are described which overcome this objectionable feature and permit more flexible operation. The various arrangements of compensators and counterweights to permit this are described.*

THE term "cargo" covers all sea-borne merchandise and may be sub-divided into:

1 Bulk cargo—grain, coal, ore, timber, oil, etc., or any other commodity, only one of which is carried by the ship on any particular voyage

2 General cargo—merchandise of all kinds, either packed in containers, baled or handled loose, a great variety of materials going into the making of one cargo.

It is the intention of this paper to deal only with dock cranes as applied to the handling of general cargoes, and not to include any of the special class of appliances which have been devised for loading and unloading bulk cargoes. In the latter class are included such machines as the Hulet unloader, coal transporters, grain elevator legs, etc. These devices are in each case designed for handling one particular class of material, the selection of the most suitable machine being determined very largely by this consideration only. For the work they are intended to perform they cannot be excelled, but their field of usefulness is confined to the material under consideration.

## Handling of General Cargo

In the handling of general cargo a very much broader view in analyzing the situation has to be taken. Diversity of shape, size and weight precludes the possiblity of using elevators or conveyors to any great extent, while the necessity of sorting and piling in alloted places on the wharf makes the transporter, with its rather limited area of discharge, unsuitable. The transporters here referred to are those of the traveling type, but without a swing or radial motion; those having a radial motion and sometimes referred to as straight-line cranes will be dealt with later.

In selecting the most economical crane for handling general cargo it must be borne in mind that individual pieces will vary in weight from a fraction of a ton up to perhaps 50 tons or over. The frequency with which 50-ton lifts are likely to be encountered is exceedingly low, also 10-ton lifts are quite uncommon, so that it would be out of reason to install on any single dock a number of cranes capable of handling such weights. The question then arises: What is the most economical capacity of crane to use? This question cannot be answered with any certainty, as no one can foretell what the average weights to be handled will be. It can be stated, however, that the most popular general-cargo cranes in use at present are of from three to five tons' capacity.

Loads above this are not so very frequently encountered, and should be handled by ships gear or by a heavy-lift crane with which every port of any magnitude should be equipped. If ships gear is used for heavier lifts than five tons it generally means that a special derrick boom has to be rigged, as the derricks usually employed will not lift such weights. Many tramp steamers carry on deck a heavier boom and tackle which can be rigged on the mast for taking extra-heavy lifts. The erection of this special equipment entails both expense and delay, which should not be required in any well-equipped port.

In addition to considering the different weights which have to be handled, the great variety of sizes must be considered. This does not apply so much to case or baled goods, but is particularly noticeable as regards the type of crane to be adopted when it comes to loading or unloading such material as steel rails, structural sections, iron rods, and long timbers. In lifting material of this nature into, or from, the hold of a ship it is necessary to place the slings in such a position that the load will assume a more or less vertical position when lifted. The result is that a good portion of the load will project above the hook, and when in its highest position will project above the hoisting pulley.

In the case of derricking jib cranes, either level luffing or otherwise, this is not important, as the jib swings with the load; but with the transporter or straight-line crane, that portion of the load projecting above the trolley path is in danger of fouling the boom as the trolley is racked in or out. A slight shock to a bundle of rails, rods or angles will often cause the load to slip through the sling.

A further point to be considered in the handling of general cargo lies in the fact that different consignments are often loaded promiscuously into the sling nets and have to be sorted as to marks and numbers when landed on the wharf so that each consignment can be piled in its allotted place in the sheds or on the dock. Then again it may be required to take one class of material from one part of a ship's hold and another class from a different part of the same hold and deliver the loads alternately to two separate shed doors. In order that the same crane may be capable of this duty it should have a wide area of pick-up and discharge without delay being occasioned in reaching these areas.

An important consideration in selecting a wharf crane is the

[1] Local manager, C. C. Moore & Co., Engineers, Vancouver, B. C. Mem. A.S.M.E.

Contributed by the San Francisco Section and presented at the Seattle Meeting, Seattle, Wash., August 29 to 31, 1927, of The American Society of Mechanical Engineers, 29 West 39th Street, New York.

wheel loads which the structure of the wharf will be subjected to. As will be seen from the accompanying illustrations these wheel loads may vary to a very considerable degree in different makes of cranes, although they may be of the same capacity, outreach and rail gage. These wheel loads are not quite so important in determining the selection of crane in cases where a new wharf is to be built, as provision can be made for whatever loading is required, but in cases where cranes are to be installed on existing wharves great care must be taken to see that the maximum wheel loads will not be in excess of the safe working loads the wharf structure is good for. In any case the crane with the smallest

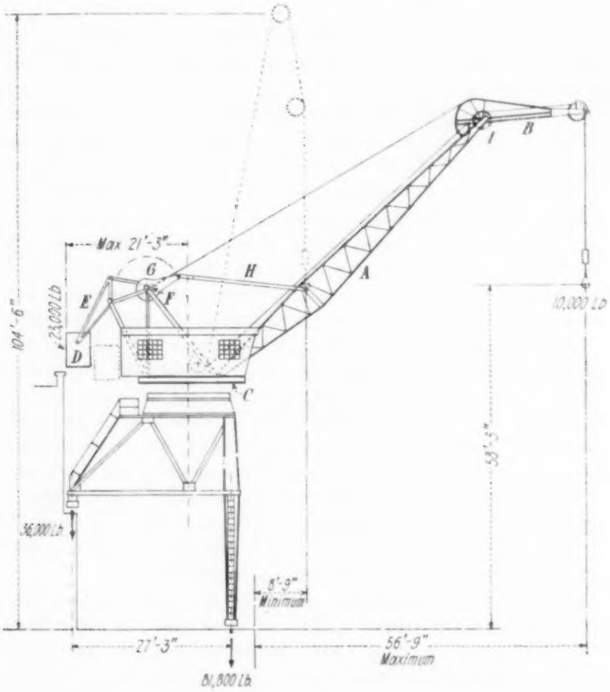

Fig. 1 Level-Luffing Type of Crane

wheel loads, other things being equal, has a decided advantage over others. Any additional strength to a wharf or building, whether new or otherwise, required by reason of the wheel loads it is subjected to should be debited against the crane when selection is being made.

The hoisting rope of a modern cargo crane should lift on a single fall of rope, even when dealing with loads as high as five tons, as the handling of a snatch block in the hold of a vessel is a clumsy and aggravating process and is strongly objected to by stevedores and laborers. The bight formed by the snatch block is very liable to catch in anything that may project into the hold of the ship, also the two strands of the hoisting rope may possibly get twisted one around the other and require untwisting before the load is picked up. This is one of the disadvantages of the type of crane shown in Figs. 7 and 8.

How the different types of cranes fit in with the above requirements will be seen later on.

Before coming to a description of any of the modern wharf cranes at present in use it might not be amiss to review briefly some of the earlier types and the circumstances which have lead to their betterment.

## Early Wharf Cranes

Omitting the very primitive contrivances, we find that the earlier wharf cranes were very often stationary jib cranes having a fixed radius, either steam or hydraulically driven. These had many disadvantages, as can easily be seen, and if in use today would not compare favorably as to speed with any ships gear. They had their use, however, in the days when sailing ships were in the preponderance.

A more recent development was the traveling portal crane having a jib capable of being luffed as well as swinging. In this type all the required motions were present, but there was still much left to be desired. Those that were steam driven had the disadvantage of the time wasted in getting up steam, the necessity of constant firing, supplying of coal and taking away of ashes. Hydraulic power, on the other hand, had to be transmitted from a central source to the crane through a pipe line, and although hydraulic cranes were made to travel along wharves to a certain extent the amount of travel was very limited. Also, there was the trouble of frozen pipes, cylinders, etc.

Next came the electric crane, first operating on direct current, then alternating current. These constituted a big step in advance of the steam or hydraulic crane. At the same time

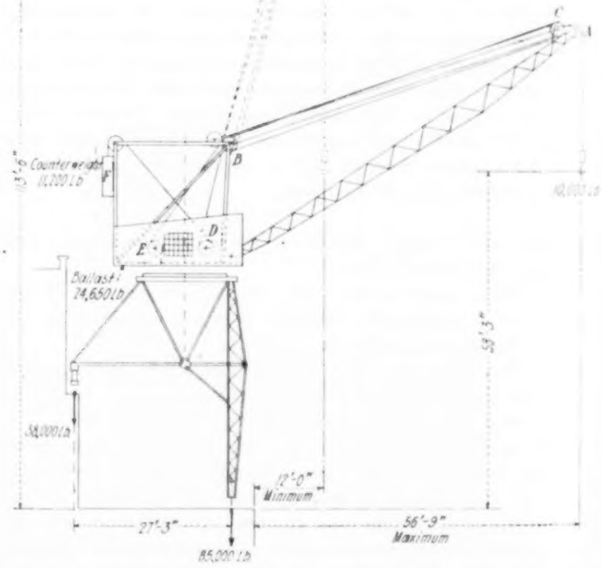

Fig. 2 Level-Luffing Type of Crane with Special Reaving of Hoisting Rope in Conjunction with Particular Arrangement of Centers of Jib-Head Sheaves, Fixed Sheaves on Superstructure End of Jib-Foot Pivot

that wharf cranes had been advancing, however, a certain amount of improvement had been made in ships winches and the methods of using them, so that there was not a very great difference in the speed of handling cargo by cranes as compared with ships gear.

In spite of the fact that up to quite recently wharf cargo cranes did not show much advantage as to speed over ships gear, they still formed a very important part of the dock equipment of many large ports. One of the principal reasons for this being that, providing wharf cranes are available, a ship on arriving at her home port for discharging is not under the necessity of keeping up a head of steam, with all the attendant expenses, simply for the purpose of working the cargo winches. Bearing this in mind, and remembering that up to 1921 nearly 35 per

cent of the world's ocean tonnage was carried in British ships, and 60 per cent in ships of European register, it is hardly surprising that it is in Europe that we find the cargo crane most highly developed.

### Luffing Cranes

One of the chief disadvantages which the ordinary luffing crane works under is that when the jib is luffed in the load suspended from the jib head is simultaneously raised; conversely, as the jib is let out the load falls by a corresponding amount. This is all wasted work and means an unnecessarily large motor to work the luffing gear. A further result is that the jib is luffed in or out as little as possible and the flexibility of the crane is seriously impaired.

To overcome this objection a number of different designs of a type of crane known as the "level luffing" crane have been developed. In all cranes of this type a compensating gear in some form or another is provided whereby the load is made to travel along a horizontal path irrespective of the rise and fall of the hoisting pulley caused by the luffing in or out of the jib. A well-known make of this type is illustrated in Fig. 1.

The distinctive feature of this compensating gear, which pro-

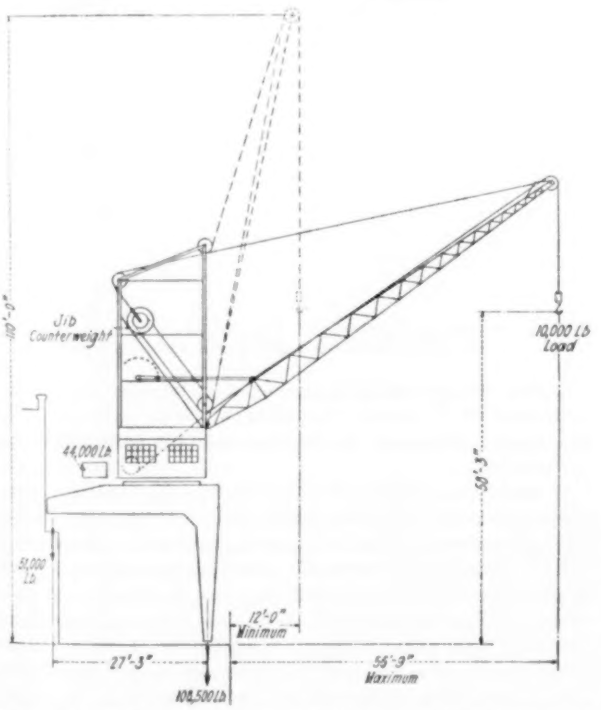

Fig. 3 Level-Luffing Type of Crane with Counterweight Arrangement for Paying Out Required Amount of Rope to Give Level Luffing

vides the level luffing motion, lies in the fact that the crane jib is composed of two sections; the outermost of which is folded in toward the other automatically as the load is luffed in, and vice versa. During the operation of luffing, therefore, as the lower section of the jib is raised at a steeper and steeper angle, the outer end folds down; the relative motions being such that the sheave at the extreme end of the jib travels along a horizontal path, the suspended load doing likewise.

Referring to Fig. 1, which illustrates a 5-ton crane of the above type, it will be seen that the main jib $A$ carries at its outer end an extension jib $B$ which is roughly one-quarter the length of $A$. The main jib is of lattice construction and is pivoted at its heel to the revolving platform.

The weight of the jib is balanced by the counterweight $D$ which is connected by the bell cranks $E$ to cranks on the shaft $F$. On the same shafts are the cranks $G$ which actuate the jib through the links $H$.

Returning to the extension jib $B$ which is pivoted on the same shaft as the sheave $I$, it will be seen that its construction includes a member curved around the inner end of $B$ in a loop. In plan, there are two of these curved members which are channel-shaped in section, in each of which a guy rope is secured and anchored back to the shaft $F$. When the jib rises $I$ approaches $F$,

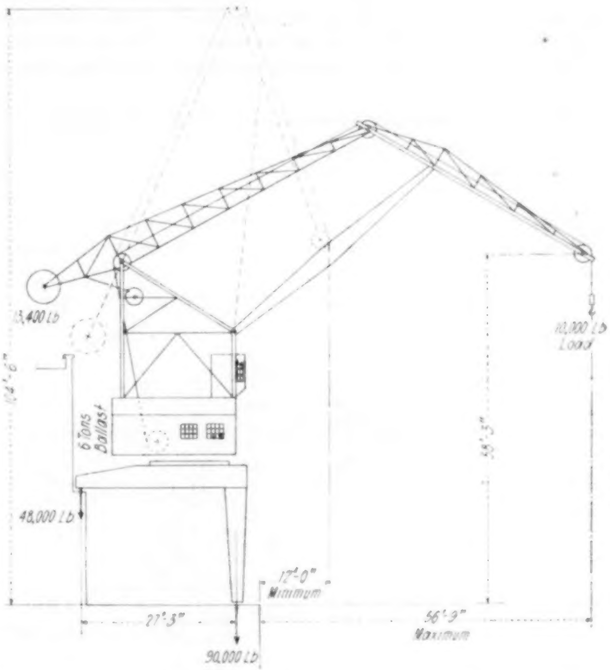

Fig. 4 German Design on Order of Pantograph with Level-Luffing Feature

so that the guy ropes allow the extension jib to rotate downward, the guy ropes at the same time wrapping around the curved channels. These channels are not bent to a true circle but are of special form so that the folding in of the extension jib is constrained in such a way that the load travels in a straight line. The small amount of hoisting rope which is paid out during luffing, due to the hoisting barrel not being concentric with the foot of the main jib, is compensated for by this means.

As the load being lifted is neither raised nor lowered during luffing operations, it will readily be seen that the power required is only that which is necesary to overcome the inertia of the parts moved.

The balancing of the dead weight of the jib also has a bearing on the ease or otherwise with which luffing can be carried out. In the type of crane shown in Fig. 1, the counterweight $D$ moves simultaneously in the opposite direction to the jib, so that the two are always very nearly in balance.

The value of this balanced level-luffing system will be appreciated from the fact that on two cranes of similar capacity and radius, that fitted with this gear will have a luffing motor of about one-tenth the power of the other, and when it is considered that in most cases the jib is luffed with every lift, it will be realized that an enormous saving in power is effected.

### Discussion of Operation

The crane shown in Fig. 1 has a maximum outreach, measured

from the face of the dock, of 56 ft. 9 in., which is equivalent to a radius, measured from the crane center, of 76 ft. 9 in., and has a minimum radius of 11 ft. 3 in.; that is to say, it can pick up or deposit its load anywhere between two circles having diameters of 153 ft. 6 in., and 22 ft. 6 in., and can place its load not only on the dock itself but also on upper floors of the sheds if so desired, a point in its favor, as compared with cranes illustrated in Figs. 7 and 8.

The jib with its counterweight and other parts which go to form the revolving portion of the crane are made as light as is compatible with safety, so that with a hoisting speed of 175 ft. per min. for 5 tons, or 300 ft. per min. for $2^1/_2$ tons and with a high slewing speed, which at the maximum is 450 ft. per min., quick action is obtained in transporting a load from one point to another.

The wheel loads indicated in the illustrations are directly comparable, as all the cranes except those shown in Figs. 5 and 6 are exactly similar as far as loads, outreach from face of dock, and speed are concerned; except also that the crane shown in Fig. 7 is designed for hoisting speeds of 100 ft. per min. for 5 tons and 200 ft. per min. for $2^1/_2$ tons, as against 175 and 300 ft. per min., respectively, for the other cranes. This difference makes the impact component of the total wheel load slightly less for the crane in Fig. 7 than it would be if the higher hoisting speeds were used.

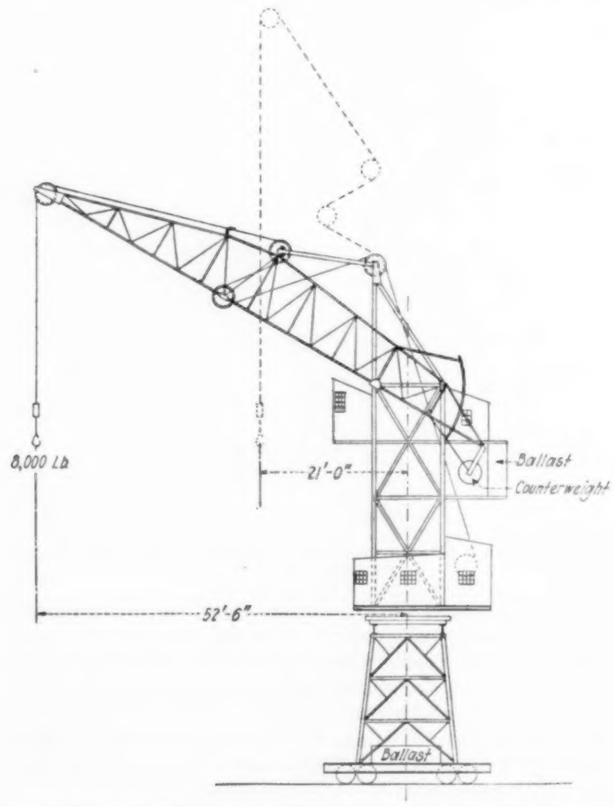

Fig. 5 Crane in Which Luffing Is Accomplished by Means of Pinions Engaging in Segmental Racks on Each Side of the Jib

In Europe level-luffing cargo cranes are now almost exclusively used, and other designs than that shown in Fig. 1 have been evolved. The arrangement for obtaining the level-luffing motion in the crane shown in Fig. 2 consists of a special reaving of the hoisting rope in conjunction with a particular arrangement of the centers of the jib-head sheaves, the fixed sheaves on the superstructure, and the jib-foot pivot. The hoisting rope after passing over the sheave $A$ at the extreme end of the jib is taken around one of the sheaves at $B$, thence back to one of the sheaves at $C$, again over a second sheave at $B$, and thence to the hoisting barrel $E$. When luffing-in the jib from one radius to another, the distance between $A$ and $B$ decreases by an amount equal to one-third of the vertical raise of the jib head. Since there are three falls of rope between $A$ and $B$, the amount of rope paid out is three times the amount by which the distance $AB$ has been decreased, and, therefore, compensates for the vertical rise of $A$.

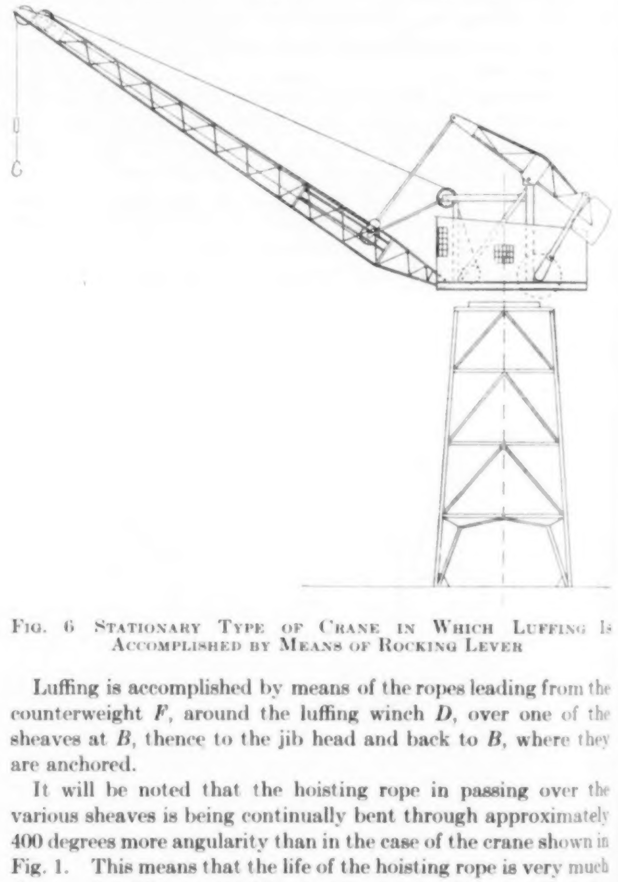

Fig. 6 Stationary Type of Crane in Which Luffing Is Accomplished by Means of Rocking Lever

Luffing is accomplished by means of the ropes leading from the counterweight $F$, around the luffing winch $D$, over one of the sheaves at $B$, thence to the jib head and back to $B$, where they are anchored.

It will be noted that the hoisting rope in passing over the various sheaves is being continually bent through approximately 400 degrees more angularity than in the case of the crane shown in Fig. 1. This means that the life of the hoisting rope is very much shortened, with a proportionate increase in the cost of maintenance. The counterweight $F$ in this crane is much lighter than that of the crane in Fig. 1. To make up for this, additional ballast is placed in the back of the operating cab, so that the total is considerably in excess of that of the first crane. Also, the crane in Fig. 2 lacks the advantage gained by the outward movement of the counterweight as in Fig. 1.

In Fig. 3 is shown another design of level-luffing crane. Here the hoisting rope, after passing round a sheave near the jib foot is taken over a sheave placed concentrically with and attached to the traveling counterweight; it is then taken back to the sheave near the jib foot and so to the hoisting barrel. As the jib is luffed in, the counterweight travels down the inclined path, thus paying out the required amount of rope to give level luffing. A crank and connecting link are used for actuating the jib.

A somewhat novel type of crane is illustrated in Fig. 4. This is of German design, in which country it has been used quite extensively. As will be seen it is on the order of a pantograph, thus obtaining the level-luffing feature.

The two cranes shown in Figs. 5 and 6 are very similar in the

means employed for obtaining the level path of travel for the hook. The hoisting rope, on its way from the jib head to the hoisting barrel, is taken in a bight round the sheave centered on the radius rod attached to the crane structure. As the jib is luffed, this sheave is made to travel along the track forming part of the jib. Except for this similarity the cranes are very different, that in Fig. 5 having the peculiarity that the lower end of the jib is so constructed that it embraces the revolving tower, and has counterweights on either side of the machinery house. Luffing

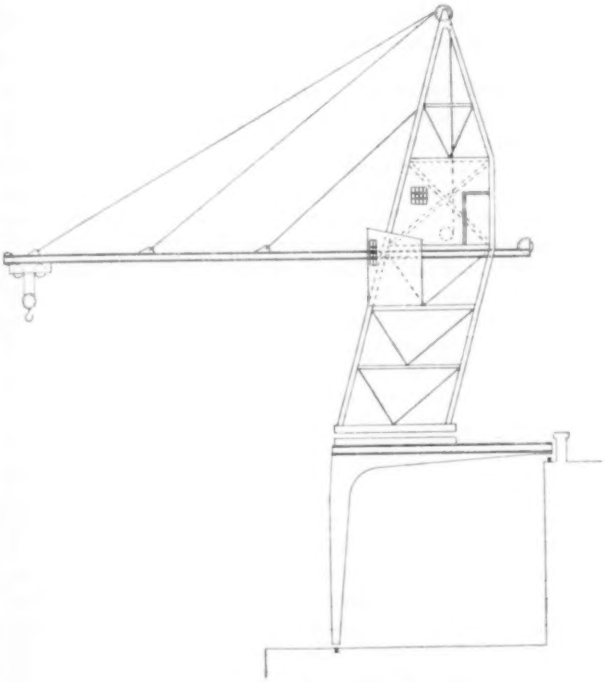

FIG. 7 TYPE OF TRANSPORTER CRANE

is done by means of pinions engaging in the segmental racks on each side of the jib.

Although the crane illustrated in Fig. 6 is of the stationary type, it could equally well be made to travel. The level-luffing motion has already been described as being accomplished by the sheave traveling up and down the path within the jib lattice work, the sheave being controlled by the radius rod. Luffing in this case is by means of a rocking lever which is attached to the jib at one end by means of a long link and at the other end is connected to a revolving crank. The rocking lever is counterweighted. An all-round motion of the luffing crank is permitted, which has the advantage of preventing any possibility of over luffing, but has the distinct disadvantage in causing confusion for the operator in his not knowing in which direction the jib will move from a point of rest. The crane in Fig. 1, although equipped with a crank-actuated luffing device, does not have the all-round motion as above described, limit switches being provided to prevent the operator luffing the jib in or out beyond certain limits. It still has the safety feature of not permitting over luffing should the limit switches fail.

In Figs. 7 and 8 are shown cranes of the transporter type, that shown in Fig. 8 having the advantage over the one in Fig. 7 in that the load may be transported to the rear of the machinery house. This is accomplished by offsetting the trolley rail from the center line of the jib by an increasing amount as the rail leaves the jib head and approaches the main structure. At the center line of rotation of the crane the trolley rail is sufficiently offset for the trolley and its load to pass the substructure. The amount of this offset determines the minimum operating radius of the crane. The type illustrated in Fig. 8, on account of the offset, approximately 17 ft., has a greater minimum radius than that in Fig. 1.

It might appear that once this type of crane had been put into position, with its jib head in the correct position over the ship's hold, a greater unloading speed could be attained than with a luffing crane, by reason of the fact that the load after being hoisted travels in a straight line to the point of discharge instead of traveling in a more or less circular path as in the latter case. It should be observed, however, that whereas the crane in Fig. 8 has a racking speed of 250 ft. per min., the slewing speed of the crane in Fig. 1 has a maximum of 450 ft. per min., and an average of 277 ft. per min.

In addition to this the level-luffing crane is almost invariably luffed at the same time that it is being slewed, in this case at a rate of 150 ft. per min., so that there is the accumulation of the two speeds.

The type of crane shown in Fig. 8 is seldom slewed through any considerable angle once it is in position, the reason being that when it is rotated it cannot describe an arc of shorter radius than the length of its jib measure from the center of the crane. As a

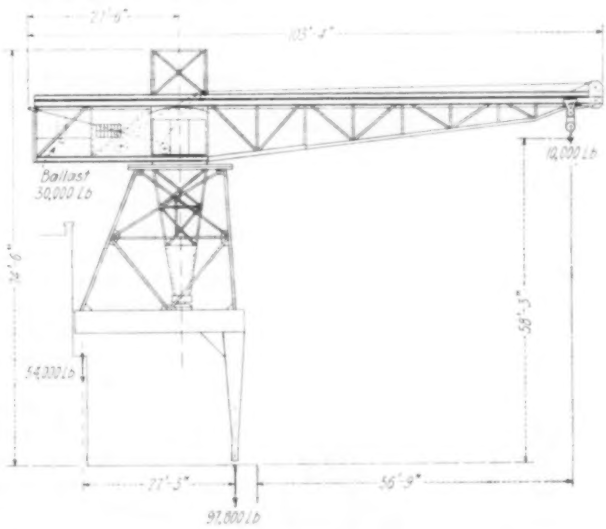

FIG. 8 TRANSPORTER CRANE IN WHICH LOAD MAY BE TRANSPORTED TO REAR OF MACHINERY HOUSE; A FEATURE NOT INCORPORATED IN THE CRANE OF FIG. 7

result it will often foul the ship rigging or upper-works on being slewed, unless it is at the same time traversed along the dock. Traversing is comparatively slow and sometimes requires clearing of the tracks before the crane can be moved. This, however, is the procedure adopted when it is desired to land loads alternately at different points on the dock. The first load is deposited in its assigned position, then after picking up the second load the crane is traversed along the dock until the second load can be dropped

TABLE 1 PRINCIPAL DATA ON CRANES ILLUSTRATED

| Fig. No. | Total weight, lb. | Hoisting speed, 10,000 lb., ft. per min. | Hoisting speed, 5000 lb., ft. per min. | Slewing speed, r.p.m. | Luffing speed, horizontally, ft. per min. | Maximum wheel loads, two-wheel bogies, lb. |
|---|---|---|---|---|---|---|
| 1 | 127,000 | 175 | 300 | 1.5 | 200 | 81,800 |
| 2 | 149,000 | 175 | 300 | 1.5 | 200 | 85,000 |
| 3 | 195,000 | 175 | 300 | 1.5 | 200 | 108,500 |
| 4 | 146,000 | 175 | 300 | 1.5 | 200 | 90,000 |
| | | | | | Racking | |
| 8 | 169,200 | 100 | 200 | 1.0 | 250 | 97,800 |

in its appointed place. While this is being done the jib head is held approximately in a fixed position over the vessel, and the cycle is then repeated as may be necessary.

From the above it will be seen that a straight-line crane is better adapted to handling material from the ship to one point at a time on the wharf rather than to different points in quick succession, as is required in sorting and piling general cargo.

The weight as shown in Table 1 is also a disadvantage of this type, not only in cost of construction but also in that a stronger and more expensive substructure is required for supporting it.

In the table are given also some of the principal data relative to the cranes illustrated, to which it should be added that they are all designed for the same load, namely, 10,000 lb., the same maximum outreach, of 56 ft. 9 in., and a hoisting height of 58 ft. 3 in., also the same rail gage, 27 ft. 3 in.

## Discussion

D. S. Beyer.[2] An important point which is not discussed in this paper is that of accessibility of parts requiring frequent inspection, repairs, lubrication, etc., and the safety of the men who must do such work.

Repairs may have to be made under difficult weather conditions, and wherever practicable, stairways should be provided. Where a ladder seems to be the only possible arrangement, it should have a safety "cage" or enclosure around it.

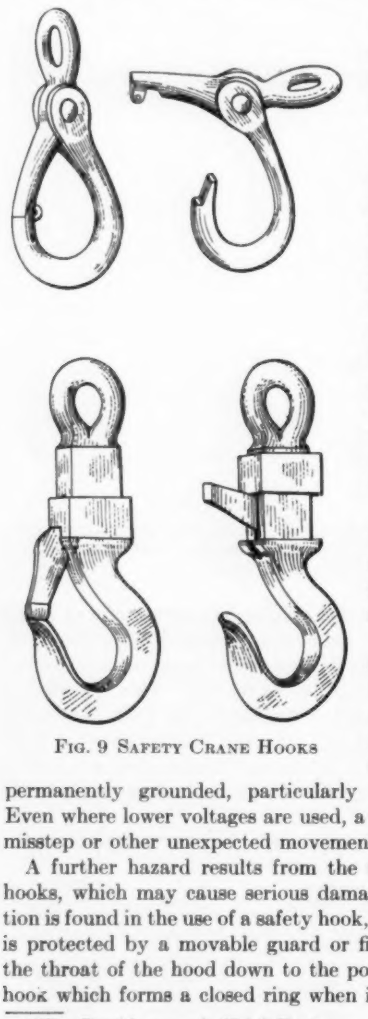

Fig. 9 Safety Crane Hooks

In many cases the provision for getting to bearings consists of a few loose planks strung here and there by riggers, or by the men who have to use them, making the work of lubrication, inspection, and repairs a constant hazard. Under such conditions this work is likely to be neglected, or injury to the men who are provided to do it may tie up the equipment.

Permanent railed walkways, with platforms at sheaves or other working points, should be provided in all cases.

Electrical equipment should be enclosed so as to prevent accidental contact with live parts. Dead metal parts such as motor frames should be permanently grounded, particularly for voltages above 220. Even where lower voltages are used, a slight shock may cause a misstep or other unexpected movement that will result in a fall.

A further hazard results from the use of ordinary open-end hooks, which may cause serious damage. An excellent precaution is found in the use of a safety hook, so designed that the point is protected by a movable guard or finger which projects from the throat of the hood down to the point, or by using a type of hook which forms a closed ring when it is in use. In the latter case the hook may be designed so that the point is supported and strengthened by the extra member which closes the hook. Illustrations of this type of hook are shown in Fig. 9 which is taken from the writer's "Industrial Accident Prevention," published by Houghton Mifflin Company, Boston.

Counterweights should be so placed in relation to the remaining equipment, as to do the least possible damage in case they should fall, and proper means of cushioning and retaining them should be provided, to prevent wrecking the equipment or endangering human life in case they should accidently drop.

Needless to say, frequent inspection of cables and other parts of the hoisting apparatus when in service is of great importance.

[2] Vice-President and Chief Engineer, Liberty Mutual Insurance Co., Boston, Mass. Mem. A.S.M.E.

Willard C. Brinton.[3] European ports use cranes for handling general cargoes for a reason not immediately apparent to most people. These ports are very old. They were built at the head of navigation in rivers when boats were small, and as ships increased in size the rivers were dredged. The bridges in many cases are very low. This makes it impossible to use floating cranes and the result is that the cranes are on the shore.

Travelers returning to New York wonder why our seaports are so far behind those in Europe in the use of cranes. They entirely overlook the fact that New York has probably more cranes than all the ports of Europe have, but that they are floating equipment instead of being on shore. The bridges being of recent construction, they are high enough to permit such equipment to pass under.

The Author. The author cannot agree with Mr. Brinton that the extensive use of dock cranes in European ports has been brought about through the impossibility of using floating cranes. For instance, Tilbury main dock at the mouth of the Thames, and many miles below any bridge, has 56 level-luffing cranes. The new Gladstone dock at Liverpool on the River Mersey, and below any bridges, is equipped with some 50 cranes; in addition to these there might also be mentioned the new docks at Dover, Bristol, as well as Bombay, Buenos Aires, and other places. Floating cranes are principally used in transporting cargo from ships' holds to lighters alongside, or vice versa, and are not suitable for unloading from ships' holds to dock. Their extensive use in New York is largely due to the fact that the docks there, which are mostly fairly old, are not of a construction that is suitable for accommodation of dock cranes.

The author agrees with Mr. Beyer that an important point with regard to cranes is the accessibility of parts likely to require repairs, lubrication, etc., also the safety of men who have to do such work. These considerations were not discussed in the paper on account of limitation of space that would be necessary to go into such matters fully. The author would state, however, that it is almost impossible to use stairways on any cargo cranes which necessarily are of the traveling type, and means of access to the crane have to be minimized as far as possible so as to make the under structure compact. Ladders with good hand railings on either side of them are, in the author's opinion, just as safe as stairways.

With regard to the safety hook, the type almost universally used in Europe is a hook which takes somewhat the form of a C, the lower portion of which, or the hook proper, is curved inward at this point so as to guide the sling should it tend to come out of the hook into the upper bend of the hook. This type of hook also has the advantage of not being likely to catch in any obstruction when it is being raised. Types of hooks which have movable guards are not only liable to get out of order but also cause delay in hooking on and off the slings.

# Bulk-Material Handling at Docks and Storage Plants

By A. F. Case,[1] Cleveland, Ohio

The scope of this paper does not include the handling of bulk commodities in small capacities, but rather the methods which have resulted in the vast production of today. In the discussion of this subject it is difficult to refrain from reviewing briefly the historical side of the development of modern equipment. The Great Lakes furnish a marvelous waterway for the transportation of the main bulk commodities, coal, ore, and limestone.

The source of coal lies adjacent to the southern end of this waterway, and the northern end extends into the greatest ore deposits in this part of the world. It is therefore logical that great fleets of ships have been constructed and equipment of high capacity has been developed to transport the immense tonnages required for modern consumption. Coal is the only material in this group used for both industrial and domestic purposes. The industrial demand in the districts of Pittsburgh, Youngstown, Cleveland, and Buffalo is served by rail.

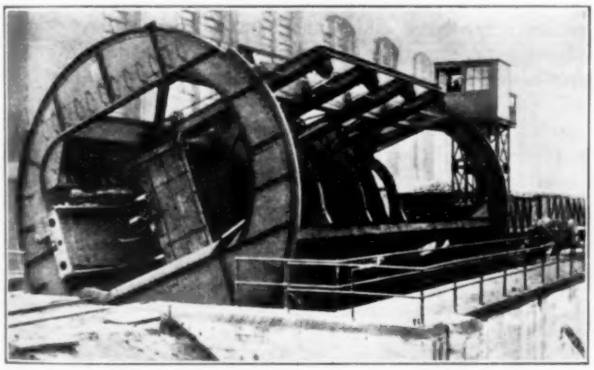

Fig. 1 Revolving Car Dumper

Detroit, Chicago, and Milwaukee use considerable industrial and domestic coal, but the upper lake region is the center of the vast domestic market, and the ports of Lake Superior are the destination of the large shipments from the lower lakes. This then is the background of our picture—coal cargoes from the lower to the upper lakes, and ore cargoes returning.

The first coal cargo was loaded into lake vessels in 1850 at Cleveland from the Mahoning valley by canal boats. This was first unloaded by hand and carried in wheelbarrows to a storage area on the dock, afterward being again handled by wheelbarrows on to the deck of the ship and dumped through the hatch into the boat. The boats at that time had capacities up to 150 to 250 tons and took about a day to load, using all the men as advantageously as possible.

It was not long before larger cargoes were required and mechanical handling methods were installed. This first took the form of revolving derricks designed to handle 1-ton tubs. These tubs were filled by hand and held by a catch which was tripped by pulling a cable attached to a latch. This was between 1875 and 1880. The size of these buckets was subsequently increased to 5 tons by 1892.

The use of revolving derricks was continued until 1890, when the first car dumper, the Lindsley, was placed in operation at the docks of the Cleveland, Canton & Southern Railway at Cleveland. At this time the car capacities were very much less than at present, ranging from 10 to 20 tons. There was a tendency, however, to use larger cars, and the old machines proved inadequate. The car-dumper art passed through several phases after Lang began to handle cars, and developments followed rapidly. In 1896 the first lifting car dumper was put in operation and was immediately successful. Modifications of this dumper are in use today.

The fundamental operation of these machines follows the practice of pushing the cars up an inclined approach by means of a mule car or larry and spotting on the car-dumper cradle, which is lifted to a predetermined height, when it is inverted, and the coal runs into a pan extending over the boat. This pan is contracted at the outer end, and a telescope chute is used to direct the coal into the boat. After discharging the coal the car is returned to its upright position and lowered by gravity to the starting point, where it is bumped out of the cradle by the next loaded car coming in. The empty car then runs down the discharge track into the empty storage yard.

Fig. 2 Coal-Loading Pier With Lifting Car Dumper, Revolving Car Dumper, and Conveyor

The modern machines have been greatly refined, but many of the original principles have been retained. All these original machines were steam operated. The first electrical operation applied to a car dumper for loading boats was at Baltimore in 1921 on the coal pier of the Western Maryland Railway Company. This was followed in 1926 by an electrically operated machine at Toledo, Ohio, on the Ohio Central Railroad Company dock.

This machine is the most modern of its type and has several interesting features. It is the first electrical car dumper of the lifting type installed on the Great Lakes. The operation of the mule and cradle motions employs the Ward Leonard principle of generator field control, and the cradle is over-counterbalanced so that the amount of power required is about the same to raise the loaded car as to lower the empty car after dumping.

The constantly increasing size of cars and capacity demands have required the special features described. The Toledo

[1] Manager, Ore and Coal Division, Wellman-Seaver-Morgan Co.

Presented at the First National Meeting of the A.S.M.E. Materials Handling Division, Philadelphia, Pa., April 23 and 24, 1928.

machine is designed to handle forty 120-ton cars per hour. These cars when empty weigh 41 tons, and loaded, 160 net tons. The problem of handling cars of this capacity was solved by applying counterweights in such a manner that the effort acts directly on the cradle to balance part of its deadweight when lifting, and also on the drums which operate the cradle-hoist system. The horsepower is thus reduced to about 900 for the cradle hoist as compared to about 1700 hp., which would be required to obtain the same capacity by previous methods of counterweighting. The mule-haulage function of this machine also requires but 900 hp. The generator field control also effects considerable saving in current consumption. In fact, the total current per ton of coal handled in 70-ton cars during the season of 1927 was only 0.24 kw-hr., and this would be considerably reduced if larger-capacity cars were handled.

Coal handling on the Great Lakes is an industry in itself, but enormous quantities are also handled at Atlantic seaports. Norfolk, Va., is probably the largest of these. The Norfolk & Western, Chesapeake & Ohio, and Virginian have extensive

Fig. 3 Electric 80-Ton Coal Transfer Car

facilities. These differ greatly from the plants on Great Lakes ports, employing simple turnover car dumpers which empty the material into transfer cars of 100 to 120 tons capacity. These cars are elevated to tracks on the top of huge pier structures with pockets and chutes for discharging into ships. The cars are self-propelled and provided with discharge gates at the bottom through which the coal passes into the pier pockets.

On the new pier of the Virginian Railway the pier structure differs in that movable loading towers carry the pockets into which the transfer cars discharge, and steel conveyors on booms extending over the hatches of the ships carry the coal to a telescope through which it passes into the ship's hold.

Baltimore is another port of importance and probably possesses a greater variety of coal-handling equipment than any other Atlantic port. The Baltimore & Ohio equipment at Curtis Bay consists of two turnover car dumpers which discharge the contents of road cars on to belt conveyors, which serve movable loading towers provided with shuttle conveyors carried on adjustable booms which may be extended to either side of the pier for loading purposes. The Pennsylvania Railroad at Canton is equipped with a single car dumper which discharges into small cable cars traveling on an elevated trestle extending the full length of the pier. These cars are automatically tripped and their load is discharged into the hoppers of movable loading towers similar to those on the Virginian pier.

At Port Covington the Western Maryland Railway has a 100-ton electrically operated lifting car dumper on the pier in a stationary position and arranged to load directly into boats. Coal may also be diverted through a bypass chute arrangement and conveyors to a stationary loading tower on the opposite side of the pier.

Recently a new facility has been added by the Western Maryland to their plant, noteworthy in that it represents a radical departure from generally accepted methods of handling coal from cars to boats. Cars are introduced into the dumper by the standard mule-car method up an approach incline, and after being dumped they run down a gravity track to a kickback and into a storage yard. This method is common to practically all loading plants.

The car dumper in this case differs from all others by being of the revolving type; that is, it consists of a barrel structure which holds the car and turns about its own axis to dump. On account of the characteristics of this motion it is possible to control the discharge of coal into the hopper beneath the dumper so that there is practically no breakage. The material is removed from the hopper by a steel apron feeder which discharges on to a 60-in. belt conveyor. This carries it to the stationary loading tower, where it is taken by the boom conveyor and discharged into the ship. This is the first modern plant to employ the revolving car dumper, although the machine has been very extensively used in power plants and materials-handling plants remote from waterways. The cradle power requirements are very low, only 125 hp. being required to handle forty-five 120-ton cars per hour, and the power may be either alternating or direct current.

This construction included in this latest plant of the Western Maryland Railway is the first step in a revolutionary revision of modern coal-loading methods. The ideal plant consists of mule haulage, a revolving car dumper, and a loading tower with a high-capacity conveyor carried by boom extending over the ship's hatch, and a telescopic chute to conduct the coal into the hold.

Such a plant possesses advantages present in no other arrangement—low initial cost, low operating cost, practical elimination of breakage, low current consumption, low maintenance, absence of massive structures, and other features less essential. These

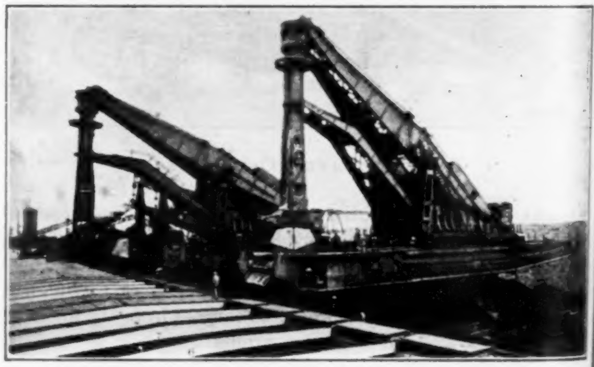

Fig. 4 Two 15-Ton Hulett Ore Unloaders

advantages are so superior that the Pennsylvania Railroad, after completely investigating all important coal-handling plants to determine the best facilities for their new coal pier at South Philadelphia, selected the revolving car-dumper equipment just described.

There are several other important coal-loading ports on the Atlantic Coast, nearly all of which are provided with the old type of lifting car dumpers. So much for the loading of coal.

The problem of unloading coal from boats on the upper Great Lakes region centers about Duluth and Chicago, where unloading bridges equipped with man trolleys handling rope-suspended grab buckets are extensively used. These bridges span large coal-storage areas which are stocked during the navigation season to supply winter demands. The coal from these storages is

handled by the bridges into screening plants, where it is screened and classified for domestic distribution.

At the plant of the Canadian Pacific Railway at Fort William, Ontario, the coal is taken from the boats by Hulett unloaders and transferred back into storage by bridges. The Hulett machine is primarily an ore unloader and will be described later.

The handling of iron ore from the Lake Superior region dates from 1854. Up to that time the total shipment of ore had come from the Marquette range, and the total tonnage was approximately 3000 tons in that year. The shipment of ore continued from the Marquette range until 1877, when 10,400 tons of ore was shipped from the Menominee range. The total yearly tonnage from that time to the present has increased by leaps and bounds, until the figure at present is between 65 and 70 million tons per season.

The original handling of this ore was by hand, as in the case of coal, but as the tonnage increased it was necessary to provide mechanical-handling methods which followed closely in the footsteps of the development in the coal-handling industry.

At present there are only two accepted methods of removing ore from ships, one being the rope-operated grab bucket handled by a suitable bridge or tower structures, and the other the Hulett unloader.

As previously stated, the traffic of coal and ore involves the shipment of coal from the lower lake ports to the upper lakes, and return cargoes of ore are brought down in the same ships. The

Fig. 5 Movable Car Dumper

loading of ore at the upper lake region is essentially different from the loading of coal. At the ore ports of two harbors, Duluth, and Superior, the ore is loaded at the mines into specially constructed hopper cars which are provided with drop-bottom doors. Trains of these cars are brought down to the loading pier, where the car doors are opened and the ore is discharged into pockets in the pier which are provided with chutes through which the ore is discharged into the hold of the vessel. On account of the multiplicity of chutes leading from these pockets, it is possible to load a vessel in a very short time as this work is accomplished entirely by gravity. Inasmuch as the breakage is not a factor in the handling or ore, this method is ideal for transferring from cars to boats.

The removal of the ore from the boats, however, is quite an-

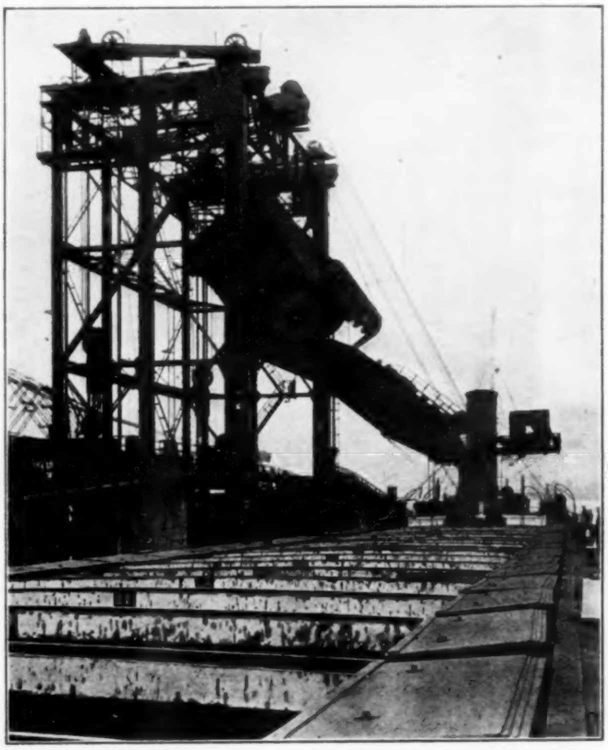

Fig. 6 Lifting Car Dumper, 120 Tons Capacity

other problem. This has been successfully accomplished by means of grab buckets operated by unloading bridges and also by small unloading towers which have been called "fast" plants. These in the majority of cases are used for unloading boats for direct shipment. When storage of ore is required it has been common practice to use unloading bridges for this purpose, but in the majority of large capacity plants the Hulett unloader has been adopted for the unloading operation.

The Hulett unloader was first built in 1898, and at that time was operated by hydraulic power in the main functions, the hydraulic power being supplied by a steam accumulator carried on the walking beam, and these machines had been in constant operation up to 1926, when they were dismantled.

This machine consists essentially of a traveling gantry framework forming a support for a trolley which travels transversely to the dock. This trolley in turn supports a walking beam, which in the forward position of the trolley extends over the boat. From the outer end of this walking beam a stiff leg is suspended, at the bottom end of which is the bucket-operating mechanism and the bucket shells. The descent of the bucket into the boat is by gravity, the forward end of the walking beam being slightly heavier than the rear end. The walking beam is raised by a mechanism at the back end of the beam which is provided with ropes passing around sheaves at the rear end of the trolley and anchored to the back end of the beam. By slacking off these ropes the bucket is allowed to descend into the boat. The opera-

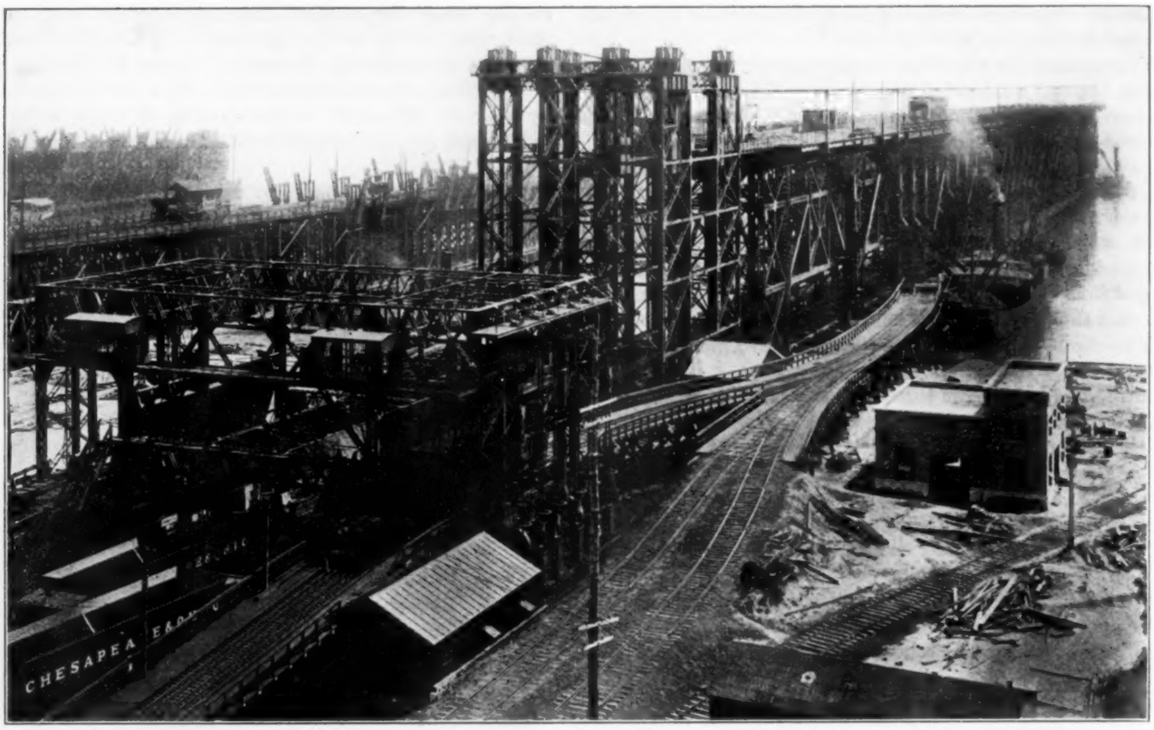

Fig. 7 Extensive Car-Handling Facilities of the Chesapeake & Ohio

Fig. 8 Five-Ton Man-Trolley Ore-Handling Bridge

tor for controlling the motions of the bucket, the walking beam and the trolley, and in some cases the movement of the total machine along the dock is in a station just above the bucket in the bucket leg, and he travels with the bucket into the hold of the boat, where he can see all of the operations of the bucket and accurately control them.

The latest machines of this type have bucket capacities of 17 tons, and in some cases the digging power of the bucket will take up 18 or 20 tons. In operation the bucket is lowered into the hold of the boat and closed in the ore. The bucket is then elevated, and the trolley runs back to a point just back of the front gantry leg, where a receiving hopper is provided into which the bucket dumps. The bucket trolley is then moved forward, the bucket lowered into the hold of the boat, and another bucket load is taken up. During the interval that the bucket is getting its second load the receiving hopper is discharged into a larry which travels on an auxiliary track on the underside of the gantry framework. This larry is usually provided with scales and is arranged so that it can be traveled over any of the tracks beneath the gantry span and the ore discharged into the cars after being weighed. In case it is desired to store this ore the larry travels back of the rear runway and discharges its contents into a temporary pile where it can be picked up by a storage bridge and rehandled into the main storage area.

In addition to the functions described, the bucket leg is also capable of swiveling about a vertical axis so that the reach of the bucket is available for cleaning up ore between the hatches. In this way over 95 per cent of the ore cargo can be taken out of a boat without the use of any hand shoveling. This is much in excess of the possibility of any rope-suspended grab-bucket machine.

Another point of advantage in the Hulett unloader is the fact that the forward end of the walking beam is just enough heavier than the back end to give the bucket proper digging power in

Fig. 9 Gantry Handling Load Back to Storage

the boat. This is about 10,000 lb., while the rope-suspended buckets of this capacity would have a weight of from 30,000 to 35,000 lb. This results in the case of the Hulett unloader in a very much smaller initial load being applied to the tank top of the boat, and consequently the boat damage is very materially decreased. Also on account of the fact that the bucket is accurately guided through the hatch there is no possibility of interference with the upper structure of the boat around the hatches.

The structure of these machines is very heavy, and the machines are more or less complicated. The results from their operation, however, are fully justified from the fact that while the mass is great the moving load in lifting the bucket is not very much greater than the ore contained in the bucket, and the movements are so deliberate without the usual shock found in other types of machines that the maintenance cost is very low. The capacity, however, is almost double that obtainable by any other type of machine. There is a handling record that was made by eight 15-ton machines at Ashtabula, where seven boats having a total capacity of 70,000 tons were unloaded in 22 hours actual working time, and another record was made in June, 1926, where five 17-ton machines at Conneaut, Ohio, unloaded 11,300 tons in two hours and twenty minutes from the steamer *James A. Farrell*. This reduced to unity makes a handling record of 970 tons per hour for each machine including all of the clean-up time. There have been instances where these 17-ton machines have unloaded over 1200 tons per hour each.

There are over 50 machines of this type in operation on the Great Lakes, and while these are not all of the size described, they represent the progressive stages of the development leading up to the present machine.

After the ore has been unloaded from the vessels at the various plants it is loaded either directly into cars or from storage into cars, and these cars are transported to the furnace plants where the ore is used. The removal of ore from these cars is usually accomplished by means of our car dumpers which are divided into two classes, the movable class and the stationary class.

With the movable type of dumper the ore is dumped direct from the car into the storage pile, usually dumping over a retaining wall between the car dumper and the storage. These movable car dumpers are not greatly different from the stationary type except that they are mounted on trucks and the machine is provided with inclined approaches at either end. Cars are introduced into these machines by means of a locomotive, and after the car has been dumped it is pushed out of the machine by the next incoming car and the empty runs out on the discharge track, to be subsequently picked up in a train by means of a switching locomotive. These machines are of course electrically operated and travel lengthwise to the storage yard so that they can be spotted opposite the point where it is desired to store the particular kind of ore which is being handled.

When the stationary type of dumper is used, the ore is usually dumped into a transfer car, which after receiving its load travels over a trestle system and discharges from the trestle into the storage yard or into furnace bins. The fundamental principle of these car dumpers is about the same in all cases.

After the ore has been discharged either by the movable car dumper or by transfer cars into the storage space, it is rehandled by means of bucket-handling bridges into the main storage pile and again rehandled into furnace bins when required or is rehandled for the purpose of shipment when stored in temporary areas.

## Discussion

Ed. F. Mullin.[2] One point that the author brought out was that the capacity of the rotary type of car dumper was 45 cars per hour. That would lead one to believe that he must have a large capacity to consider a dump of that type, but that is not so. We know of several installations where a comparatively low rate of capacity has warranted the rotary dump because it is an economical installation in the first place and it dumps very quickly. In one installation that handles about 2000 tons a day they will dump all that coal in about three hours, whereas by the old method with ordinary track hoppers it required from 12 to 20 negroes shoveling 10 or 12 hours a day. The horsepower for operating the rotary-type dump of course is very low.

# Fundamental Principles in Materials Handling

By HAROLD VINTON COES,[1] NEW YORK, N. Y.

THERE comes a time in almost every industry sooner or later when the economic forces shift with relation to each other and produce results for better or for worse. When this situation arises or is foreseen, emphasis must then be placed on the analysis of those factors that are causing the difficulties which confront us. In any given industry this may mean a readjustment of the capital structure; of methods of distribution; of extracting, processing, or fabricating; of the types, utilization, and compensation of labor; of equipment and methods; of the overhead structure and of the personnel of the organization.

I think it may be taken as axiomatic, although unfortunately not yet so recognized by industry or executives as a whole, that group understanding, group cooperation, and group statistics are now vital to the successful conduct of any industry and of the several entities in that group. No intelligent mariner would now think of navigating a ship without adequate data, technical equipment, and authentic charts, yet we in industry have to navigate altogether too much on the yet inadequately charted seas of business.

Again it can be taken as axiomatic that no industry can long continue on a price basis alone or without adequate profits.

There is an economic law that the price of any given commodity tends to approach its cost of production, but it should be noted that "cost of production" as used in this law includes all legitimate costs of extracting, processing, production, and distribution, and a reasonable profit as well.

It should be noted in passing that profitless prosperity is not confined to any one industry, but is prevalent in entirely too many at the present time. This problem is engaging the attention of some of the keenest minds in the country in all lines of business.

## Mechanization of Industry

The discussion, however, will be limited to merely one phase, the mechanization of those operations still performed by hand labor that come under the category of materials handling. The author will endeavor to sketch briefly some of the fundamental principles of materials handling, which in their broadest aspects can be and should be recognized and applied to any industry where a materials-handling program is to be worked out.

## Surplus Labor in Industry

There is a question that naturally will arise in many of your minds, namely, "Is this going to reduce the number of operatives per industry or per unit of industry?" Frankly, yes, and it should if we are to continue to raise our standard of living; and by that I mean not only greater wealth per capita but more leisure per capita. For I am not one of those who believe it is necessarily important for one to work laboriously six days a week to keep one's soul from becoming claimed by the devil.

We have several instances of this reduction of personnel per unit of product. For instance, the *Iron Age* in its issue of July 28, 1927, made reference to this factor in the automobile industry as follows: "While one of the leading automobile plants required 17,000 workers in 1916 to turn out 650 cars a day, today the present force is approximately 15,000 and this force has no difficulty in producing 1500 cars a day. Worked out another way this means that in 1916 it took 26 man-days for each car against 10 man-days under present conditions. Installation of machinery for cutting down both time and labor, employment of mechanics and department heads specially trained in the work, proper routing of manufacturing operations through the plant, modern equipment for materials handling, and more exact methods of manufacture through the use of more accurate machines, all taken together account for this great improvement in performance."

Mr. C. S. Ching, president of the American Management Association, in a recent address before that association comments on this situation, in so far as the tire industry is concerned, as follows. "It has frequently been said that this industry was among those which had so greatly expanded its plant that it was now unable to operate to capacity. Now the truth of the matter is that tire production in the past five or six years has been far greater than during the war period, or for that matter in the two-year business boom following the war. If we were producing tires at the same rate per employee and required the same plant equipment for each tire manufactured as formerly, the present number of employees and plant equipment would have to be more than doubled."

## Absorption of Surplus Labor

The next question is, "What is to become of this labor that is released?" Let us ask ourselves the question, "What became of the labor released by previous mechanizations in agriculture, industry, mining, etc. The reaper and harvester released labor, and so did the sewing machine, the cotton gin, the typewriter, gigantic ore excavators, etc. This labor was temporarily thrown out of adjustment, but ultimately it flowed into new industries that were created after this labor was made available. Where did the labor come from for the automobile industry, the radio industry? Where is the labor coming from for the rapidly developing aviation industry, with all the collateral developments that will certainly accompany it? Why, it will have to come, since our immigration laws are in effect a protective tariff, from the labor released by the intensive mechanization of our existing industries.

Who is so bold as to state that no new industries will be born or that man's wants are completely satisfied? Yes, we shall need this labor. It is unfortunate that we do not have such a perfect adjustment of supply and demand and control of our production and distribution mechanisms that we can immediately absorb this labor as it is released. That it always has been ultimately absorbed is a reasonable guarantee that it all will ultimately be absorbed, even though there are periods of readjustment that are difficult to deal with.

So let us proceed with the firm belief that what we are doing in intensive mechanization in our present industries is for the greatest good of the greatest number.

The problem then, stated in its broadest terms, is simply this: We must reduce our unskilled workers per industry to the veriest minimum by all the aids and skill at our command, and at the same time increase the productivity of the balance to the maximum both as to production per dollar of payroll and as to individual earnings on purchasing power.

## Cost of Handling Materials

The public is slowly beginning to appreciate the fact that the cost of living is intimately related to the cost of production and of distribution, and that one of the big factors in the cost of pro-

[1] Ford, Bacon & Davis, Inc. Past Vice-President, A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Materials Handling Division, Philadelphia, Pa., April 23 and 24, 1928.

duction and of distribution is the enormous toll due to handling, picking up and putting down, and rehandling the materials of agriculture and industry. Think of it! a manufacturer of agricultural implements in a modern plant estimated that he had to handle 108 tons of materials for every ton of finished product f.o.b. his plant!

Before the war the railroads normally handled about 1,000,000,000 tons of miscellaneous freight annually, and the seaport terminals handled about half as much more as package freight, or 500,000,000 tons. It has been estimated that adequate materials-handling devices could handle this tonnage at a reduction in cost of $400,000,000 annually. If this saving could be distributed equally per family it would represent an annual saving of $16 for every family in the United States. What this saving might be if the enormous tonnage handled annually in industrial plants could be similarly reduced in cost is problematical; that it is several times $16 per family per year is unquestionable. I have estimated it at $400 per family per year.

A survey made for a leading trade paper a year or two ago indicated that the materials-handling labor cost to American industry was 22 per cent of the total annual payroll of the American manufacturing industries in 1923, which was $14,017,107,000; and 22 per cent of this amounted to $3,084,000,000.

Eugene B. Clark estimates that manufacturers in this country pay for moving materials within their plants 80 per cent of what they pay for freight, express, and parcel post annually.

It took decades and armies of men, thousands of whom perished on the job, to build the pyramids or the ancient South American structures; yet we build structures of similar dimensions and of infinitely greater complexity today with hundreds instead of thousands; in a year or two, instead of decades. How? By perfection of labor-saving devices and organization.

It can be taken as axiomatic that nothing is where you want it or where it must be finally placed in so far as raw materials are concerned, and usually in so far as finished goods are concerned, so that the pyramiding of tolls on account of the handling of the rawest of raw materials to the most finished of finished products is enormous.

### Human Wants

Now the starting points of the supply of human demands are the raw materials of nature in the animal, vegetable, and mineral kingdoms, in the air or on or under the earth's surface or the waters thereof.

We now have the rough dimensions of our problem of supply, what are the factors in it, economic, psychological, political, and engineering. It is necessary to determine the economics of the situation in order to decide as to what investment is justified. Frequently the opposition in the change from the old methods to the new devices is psychological owing to a misconception of the effect of the program on an individual or a group, or it may be because of plant or labor-union politics, and again it may come from lack of appreciation or from misconception.

### Some Important Facts in Materials Handling

Suppose we set down the known facts such as will guide us properly to a correct solution of the materials-handling problem and the right use of materials-handling devices.

*New-Plant Operation.* In a new industrial undertaking materials handling is an important factor in determining

(*a*) Plant location
(*b*) Plant layout, present and future
(*c*) Departmental layouts and sequences
(*d*) Production equipment, layouts, and sequences
(*e*) Plant output
(*f*) Operating costs per unit of product.

Obviously for a minimum investment and lowest cost of operation consistent with the present state of the art the new plant should be so located as to take full advantage of all the natural advantages available. The materials-handling methods and devices should be sufficiently worked out at the time the plant is designed so as to make them an integral part of the design.

An industrial plant is not a box in which you dump in the three "m's," money, men, material, shake them around, and precipitate finished products. It takes brains, knowledge, and experience to properly design, build, equip, and operate an industrial plant. Why therefore perpetually handicap the business by embodying in unyielding bricks, mortar, steel, and concrete at the start, conditions which make it economically impossible properly to install and operate adequate materials handling equipment? Yet it is being done every day.

*Existing Plant.* In an existing plant the proper selection of adequate materials handling equipment will

(*a*) Increase the output
(*b*) Lower the cost
(*c*) Facilitate administration and management.

### Important Principles

Every element of materials-handling equipment should be selected not only to perform the work at present but in most instances, except in specifically isolated cases, to fit into the program conceived for the ultimate plant or the rehabilitation of the existing plant.

Eliminate all unnecessary handling operations; perform all necessary handling operations by gravity wherever economically possible. This statement seems almost axiomatic. Yet it is no uncommon thing to go into a plant and see laborers performing operations that are totally unnecessary, many of which could be eliminated at a very moderate expense, and some of which could be eliminated by the application of brains and planning alone.

Choose the methods and equipment for performing the necessary handling operations that will result in the lowest cost. You will find very often that your first solution of the problem does not result in the lowest cost when compared with your subsequent solution. It is therefore decidedly advisable to compare the cost per unit handled obtained from several practical methods of solving the problem, and then select the methods and equipment that will result in the lowest cost.

Choose standard proved and tried equipment wherever possible. Few businesses can afford to divert the efforts of the organization or the facilities of the plant to experimenting to produce a new materials-handling device unless the nature of the product and the processes or the intermediate operations are such as to render it advisable to design devices to suit conditions that equipment now on the market cannot successfully meet. Otherwise it is decidedly better to endeavor to solve the problem by the selection of known and proved equipment.

In a new plant the materials-handling devices and equipment should for lowest investment costs be an integral part of the plant in many instances. In designing a new plant and in selecting a site for one every natural advantage that can be called to aid, either in eliminating the amount of material that has to be handled or the length of the travel, should be utilized. Frequently gravity can be made to do a large portion of the work, in which case slides, chutes, rollways, bins, and the like usually can be made an integral part of the structure.

Provide for flexibility so that a failure of any of the materials-handling devices or equipment will not shut down the plant. In any materials-handling system the equipment required should be so arranged and selected as to provide flexibility in operation, so that production is not tied up by the failure of any element or unit of the materials-handling equipment.

The path of the material should be as direct as possible from the receiving point through processing steps without rehandling and with the minimum retrogressions in the whole line of travel. Before arranging for any system of shop or plant transportation a study should be made to see if the departments can be so rearranged as to permit minimum travel in logical sequence with the minimum of retrogressive movements. In other words, do not transport materials any farther than is absolutely necessary. Frequently a study of the departments, their relationships, and the sequence of operations or processes will show that a rearrangement can be made to advantage.

The investment must be justified by the return. It stands to reason that the return on the investment should be such as to justify it. Many of the progressive companies have a fixed policy that provides for the scrapping of any piece of equipment or process whenever it can be shown that the proposed piece of equipment or process can earn 20 to 25 per cent. Obviously this is good business.

The return should provide for adequate fixed charges. In order to show the proper return on the investment, provision should be made in calculating fixed charges for interest, taxes, depreciation, insurance, obsolescence, etc.

### What Materials-Handling Programs Will Accomplish

Properly selected and installed handling equipment will

1. Permit transferring to the capital account of the portion of overhead that is composed of indirect labor
2. Reduce the manufacturing cycle
3. Reduce the process inventory
4. Speed up, coordinate, and stabilize production
5. Facilitate the obtaining of accounting and production data
6. Substitute automatic mechanical scheduling for the former complicated expensive schedule and production systems
7. Govern the layout of new plants and improve the performance in existing plants.

W. F. Merrill, president of the Lamson Company, makes this statement: "The usual concept of industrial transportation problems has been confined to the man-saving, the labor-saving functions. True it is that this one element alone has already effected such great economics as amply to justify the time and thought spent on its development, but without minimizing the self-evident values of this one economic function, the broad principle behind the movement still seems to be but imperfectly understood and insufficiently applied to use.

"The industry of the future will in my opinion devote as much time to a scientific coordination of its manufacturing and materials-handling elements in their relation to production flow as it now denotes to the invention, design, and manufacture of its product and the machines that make it.

"Synchronized material movement and the grouping of production processes are important principles in the proper working out of the transport science in production. Systems of conveying properly applied may enhance production 10, 25, or even 50 per cent with the same man power and machine equipment.

"In the travel of material through the processing route it is on the average worked on less than one-third and often but one-sixth of the time. Work in process is thus often the graveyard of profits."

### Some Rules for Securing Materials-Handling Economies

Mr. McLain of the General Electric Company sets up the following rough list of instances where economies may be hoped for in the use of machinery instead of men, where said men are unaided by any mechanical device:

1. Where three or four men are working together on one job for a couple of hours at a time, even though the work is not performed more than three or four times a week
2. Whenever a man has to lift anything from his feet to a point above his head
3. Whenever a man has to lift more than 50 lb. from his feet to his shoulders
4. Whenever a man has to lift more than 100 lb. from his feet to his waist
5. Whenever a man has to lift more than 150 lb. from his feet to his knees
6. Whenever a man has to stand in one place steadily moving material for over 30 min.
7. Whenever a man has to move material sidewise more than 6 ft., that is, two steps
8. Whenever a man or a group of men, although moving around in a small radius, has to move more than 10 tons of material per hour.

### Selection of Equipment

One of the things that is the cause of much subsequent economic woe in the selection of materials-handling equipment for a specific set of conditions is confusion between service and mere mehcanical or electrical performance. A piece of equipment may be mechanically perfect, yet its selection for a given set of conditions be an economic crime because it is not designed to function so as to meet all of the conditions imposed and therefore operates at a loss.

The equipment companies are somewhat to blame for this situation. Rarely do their sales representatives know anything about the equipment of other manufacturers unless they are directly competing along absolutely parallel lines. It is my firm belief that the equipment manufacturer in the long run would have more friends and build up a more substantial good will if they would refuse orders as well as take them; in other words, if they would insist on selling service and serviceability rather than pieces of equipment.

### Comparative Costs

There is a serious lack of fundamental data as to costs of operation and a confusion of these costs. The Materials Handling Division of the A.S.M.E. is endeavoring to act in a coordinating and collecting capacity with respect to this phase of materials handling, and has devised and set up standards and formulas for comparing correctly dissimilar methods; this is nothing more than the application of mathematics to economics.

### Plant Transportation

We sometimes fail to realize what transportation costs. Why? Because some accountant once said that it was an overhead charge, and therefore it is buried in that sink hole labeled "overhead." Manufacturers can tell you exactly what their raw materials cost, how much they use, what their losses are, etc., and similarly with labor; and yet very few have set up the machinery to know what their shop transportation actually costs them.

When you once take the transportation problem apart, study the equipment, methods, rolling stock, right of way, dispatching, commodities handled, and assess the costs properly, you will usually get a shock.

There is hardly an industrial plant where costs cannot be reduced, without necessarily reducing wages, and one of the little gold mines in which I recommend you to delve is shop transporta-

tion in its broadest sense. You will frequently find that the outside consultant can bring to bear a wealth of experience in varied lines that will materially assist you to a right solution of the problem and the real dimensions of the justifiable expenditure.

There are many intangible benefits that directly accrue from the correct solution of shop-transportation problems besides the direct saving in labor. These are:

1 Reduced production space, permitting increased production in the same place
2 Lowering the cycle of goods in process
3 Reduction of inventories
4 Steadying of production and enhancing the control, resulting in better deliveries, increased sales, and more efficient purchasing
5 Speeding up of labor, since machines and men are not kept waiting for material
6 Better cost and production records.

Occasionally one meets a reactionary, who immediately objects to materials-handling methods because it adds complication to his plant. Complication! If you could see the complicated maneuvers some of them go through to obtain production, you would immediately say, "Yes, we'll resort to the paradox of adding complexity to complexity to attain simplicity." That may be too deep for some of the reactionaries.

### Reliability of Equipment

Tried and proved materials-handling equipment produced by reliable manufacturers is just as dependable in performance, and in freedom from breakdown, and just as economical in operation and maintenance as the productive equipment proper. Few charges to the contrary can be sustained. If breakdowns occur, if maintenance is high, it is owing to a lack of care, to improper selection of the units in the first place, and to overloading the equipment.

### General Situation in the Coal Industry

The general situation in the coal industry is no different from that of other industries. You have a given fixed investment, a given amount of fixed charges. If you can reduce your processing cycle by reducing the total time it takes to get out a ton of marketable material and get it on the market, you have increased the turnover of your fixed assets. You may have increased your processing indirect expense by the amount of additional fixed charges on materials-handling equipment, but you have decreased your direct expense, and the net result is a reduction in cost per ton of marketable material.

For example, an attempt was made to market coal from a vein in a drift mine by simply dumping the raw coal into cars. The coal was so dirty, however, as to be practically unusable and unsalable. A modern tipple with elevating, conveying, crushing, screening, and washing systems was installed. While it added much to the cost of handling, yet it so improved the product that it found a market at satisfactory prices. Now to have cleaned and graded this coal by hand, even in the low-cost-labor district where this mine was located, would have been prohibitive.

I am unaware of the average labor cost per ton of mined coal, but I believe that 65 to 70 per cent of the total cost f.o.b. the mine would be a fair assumption and come reasonably close to the facts.

The Carnegie Institute of Technology in its Bulletin No. 17, "Mechanical Loading in Coal Mines," shows that average savings of 37 per cent can be made by the use of loading machinery. This average is obtained from a range of 49 per cent, when a high wage scale is used, to 22 per cent for a low wage scale. For scoopers and conveyors, the loading in thin beds, average savings of 35 per cent can be made. This was obtained from a range of 40.3 per cent in high-wage-scale districts and 23.4 per cent in the low-wage-scale districts.

At my request W. K. Liggett submitted four typical examples of labor cost per ton of coal produced at the mines (Table 1).

TABLE 1

| Operation | Example 1. $6^1/_2$-ft. vein, drift mine, Pennsylvania, non-union | Example 2. 4-ft. vein, drift mine, West Virginia non-union | Example 3. 5-ft. vein, shaft mine, Indiana, union | Example 4. 6-ft. vein, shaft mine, Illinois, union |
|---|---|---|---|---|
| Cutting | \$0.12 | \$0.11 | \$0.14 | \$0.14 |
| Loading | 0.41 | 0.48 | 0.81 | 0.80 |
| Miscellaneous day labor underground | 0.13 | 0.16 | 0.30 | 0.30 |
| Miscellaneous day labor above ground | 0.12 | 0.15 | 0.24 | 0.24 |
| Total | \$0.78 | \$0.90 | \$1.49 | \$1.48 |

It will be noticed that the loading cost in the non-union mines was $52^1/_2$ per cent and $53^1/_2$ per cent, and in the union mines was $54^1/_2$ per cent and 54 per cent, so that regardless of the wage scale the loading cost was better than 50 per cent of the total cost in each case. This portion of the processing then would seem to indicate an opportunity to apply mechanical appliances and intensive materials handling, for if this cost could be lowered 40 to 50 per cent it would effect a material reduction in the total labor cost, and hence in the total cost of production. I have cited these cases simply as indicative of the mode of attack used in industry when confronted with similar problems.

Mined coal handled with locomotive cranes, for example, shows an average cost of 18 per cent of the hand operations, after including liberal charges for maintenance, fixed charges, and operating costs.

Economy in moving material, then, is secured as a rule by not moving it by hand.

The cost of production of most products is almost directly proportional to the cost of handling the various materials, direct and indirect, used in the process, be it extraction or manufacturing industry.

Material in traveling through the processing route is worked on (i.e., direct labor operations) on the average from 30 to 40 per cent of the possible time, and frequently only 15 to 20 per cent, so that it behooves us to analyze our work-in-process accounts and see what is buried in them and what can be done to increase the turnover. Proper materials-handling programs and equipment are usually the answer.

# A Materials-Handling and Transport Organization

By C. A. Fike,[1] East Pittsburgh, Pa.

*The paper outlines briefly the organization which has in charge the materials-handling activities of the Westinghouse Elec. & Mfg. Co. at East Pittsburgh. It describes the equipment used, the operation of it, and the methods of its control, and several of the wage-incentive plans which are used in the payment of the employees of the Plant Transportation Department. The paper concludes with a statement of some of the economies resulting from the organization described.*

Materials-handling activities are considered of sufficient importance in the Westinghouse Elec. & Mfg. Co. to justify the existence of a separate department whose responsibility it is to transport all material within the works in the most efficient and economical manner. It is the purpose of this paper to outline briefly this organization, its operation, method of control, and several of the incentive payment plans used with some of the economies resulting from them.

The combination of the various means of material transport, such as trucks, cranes, elevators, etc. into one department makes possible quicker and more efficient service, for in most cases material is handled by more than the one transportation means before it reaches the shipping floor in its finished state. Thus, with the various units closely linked together and under one control, no time is lost in transfer and the proper method is used at the right time. This in itself is an argument in favor of centralized control of all material-transportation activities, for in considering materials-handling problems, no general engineering formula can be applied, but all available means of transportation, and their relation to one another, must be considered before the best solution can be reached.

## Organization and Equipment

The materials-handling department at the East Pittsburgh Works of the Westinghouse Elec. & Mfg. Co. is called the Plant Transportation Department. This name in itself pretty well describes the function of the department. Materials-handling may be divided broadly into two general classes: first, that within the individual manufacturing section where it may be from machine to machine, or from operation to operation, so that the time consumed, or a greater part of it, is usually included in the manufacturing operation; and second, the movement from section to section, whether of raw material, finished, or semi-finished apparatus. It is mostly with the latter division that the Plant Transportation Department deals.

An idea of the transportation problems at the East Pittsburgh plant can be secured when the size of the plant is considered. The longest distance for an interdepartment haul is about one and one-half miles with an average haul of about one-half mile. Most of the buildings are two story, but as an exception there is one nine-story building and three four-story buildings, making a total manufacturing floor area of more than 4,000,000 sq. ft. As can be seen, both horizontal and vertical transportation must be considered.

In addition to the main works, there are three outlying departments at distances ranging from one-half to two miles which must receive the equivalent of the interdepartment service, notwithstanding the fact that material must be handled by two different transportation mediums—motor truck and industrial truck. Also, service must be maintained with the other Westinghouse plants in the Pittsburgh district located at Pittsburgh, Homewood, Wilmerding, and Trafford. Irregular but frequent truck and taxi service must be furnished for KDKA radio station and its various studios and pick-up points.

In the Plant Transportation Department are five branches of materials-handling activities, the work of each one being coordinated and fitted in with the others by centralized control from the general office. A brief description of each of these follows.

## The Standard-Gage Railroad

On account of the size and the layout of the plant, which places railroad tracks in each building where large apparatus is received or shipped, considerable use is made of these facilities and four 60-ton steam locomotives, with about 100 cars operating over 11 miles of track, are kept busy. This work is under the control of a yardmaster and an assistant.

Fig. 1 A Loaded Industrial Railway Train Showing the Miscellaneous Nature of the Work Handled in This Way

Recently trials have been made on this work with a Diesel oil-electric locomotive which proved the economy of this type over the steam locomotive; a saving of 35 per cent in operating and maintenance costs resulting. The tendency will be to replace steam power with the better fitted oil-electric haulage units.

## Automobiles and Trucks

To take care of material movement between plants in the Pittsburgh district, other than railroad movements, a fleet of eight trucks is maintained. Where needs are regular, scheduled service is maintained; where of an irregular nature, service is furnished on request. This same fleet takes care of local incoming and outgoing city movements. In this same department is operated a fleet of eight passenger cars which takes care of relief and medical-department work, as well as taxi service for officials, which is necessary on account of the scattered layout of the plant.

Maintenance of cars and trucks is taken care of within the department, the whole of which is in charge of a foreman.

## Industrial Railway

The industrial-railway department furnishes scheduled ser-

[1] Supervisor of Transportation, Westinghouse Elec. & Mfg. Co.

Contributed by the Materials Handling Division and presented at the Spring Meeting, Pittsburgh, Pa., May 14 to 17, 1928, of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.

vice to all parts of the plant, giving such frequency of service as to furnish about eight-hour delivery between any two points in the works. The railway service is mainly intended to take care of the movement of bulky or full-load material, such as castings from storage to manufacturing sections and scrap from these sections to the scrap house. Eleven storage-battery locomotives with six hundred $2^1/_2$- and 5-ton cars, running on $8^1/_2$ miles of 21-in. gage track, serve this department. Trains are made up to 25 tons of carrying load.

This work is in charge of a foreman, who has under him group leaders in charge of each route. Car movement is controlled by a movement tag which, when attached to a loaded car by a department, gives shipping directions and authority to move the car. A detachable stub on this tag is also used in billing the

Fig. 2 A Combination of Materials-Handling Units; Crane, Industrial Railway, and Elevator

department for railway service and as a basis of an incentive wage-payment plan which will be described under another heading.

### Cranes

Cranes form a vital link in the transportation system and are located throughout the works, in all buildings, storage yards, and transfer points. There are 172 electric traveling cranes in the works, with capacities up to 100 tons, located to serve the manufacturing sections, the storage yards, scrap-metal handling, and the transfer of material from one transportation unit to another. The operating control of these cranes rests mostly within the sections in which the units are located, but responsibility for maintenance and operator efficiency rests in a separate department under a foreman.

### Elevators

Efficiency of elevators has a considerable bearing on the operation of a transportation system, for nothing detracts from high running-time efficiency of trucks, etc., more than elevator waits. During the last two years the East Pittsburgh works has practically completed the revision of its elevator facilities, with the result that all multi-story buildings are served with standard 5-ton freight elevators equipped with direct-current motors and running at 100 ft. per min. with the necessary higher speed and smaller capacity, passenger elevators. A standard body, 11 ft. long by 8 ft. wide, is used, affording ample clearance for all loads handled on trucks. The elevators are built in fire-proof wells and fitted with all modern safety appliances. Operation and maintenance of elevators is under control of a foreman, the same foreman taking charge of this who has charge of cranes.

### Industrial Electric Trucks

For shipments of partial loads at intermittent intervals where the time element is more important, a fleet of 85 electric industrial trucks is used. Control is the most important feature in determining the efficiency and economy of this service. It must be readily available to be at all useful, and at the same time, trucks must be running at all times under as full a load as possible in order to secure efficiency. These two factors do not always work together, as time is an important production element, and the ordinary inclination is to disregard load efficiency in favor of the former.

To overcome this disadvantage, the shop was divided into districts and all trucking service for each district is handled by a dispatcher who has a sufficient number of trucks under his control to take care of all wants. From a reserve number of trucks made available by the increased efficiency afforded by this plan, trucks are added to the district if the production load increases, or if the load falls, trucks are added to the reserve. Close check is kept on the truck loading and only sufficient trucks to take care of the needs are kept in service. Requests for service are telephoned in to the dispatch station, in advance if possible, and are recorded and placed on a dispatch board. From this board the dispatcher makes up his loads, combining requests when possible, and assigning the work to the trucks as necessary. Work which must be handled regularly is scheduled and taken care of by the dispatcher without any special orders. The dispatchers in turn report by telephone at scheduled intervals to the works-transportation office, stating the number of loads and the time of the oldest load on their boards; as these fluctuate the trucks are shifted from one district to another so that daily peaks are taken care of and quick service is maintained. Provision is made for securing return loads by having the trucks stop at the other district dispatch stations on all return trips. However, most of this type of trucking is confined within the district since the industrial railway, as explained, takes care of bulk distant shipments.

Material from storerooms is delivered to the manufacturing sections through the dispatch stations. The section needing material telephones its requirements to the storeroom, the requisitions charging the material to the correct accounts are made out by the storeroom, the material ordered is removed from stock, placed in the proper containers, and loaded on truck skids which are picked up by lift trucks ordered from the dispatch station by the storeroom. The material, which in a greater number of occasions is in small lots, is then delivered by one truck, rather than by each section's sending its own truck or messenger. This eliminates a large number of partial-load hauls and also reduces expensive messenger service to a minimum.

Another odd job handled through the dispatch station is the delivery of the pay envelopes from the paymaster's office to the various pay stations located in the works. This is carried out on a schedule from which very little variation is allowed, but the trucks experience no trouble in meeting the close requirements.

In addition to this regular use of industrial electric trucks, there are special uses to which they are applied, resulting in lessened material-handling costs.

Three trucks are assigned as carrying units for a shop-express plan, corresponding to a parcel-post system, which handles packages of about the same sizes and weights. Four-hour

service is given to the entire East Pittsburgh works and other Westinghouse plants in the Pittsburgh district. About 900 packages are handled per day at a cost of three cents per package.

Tiering or high-lift trucks are used in the punch-press department for the handling of dies between machines and storage.

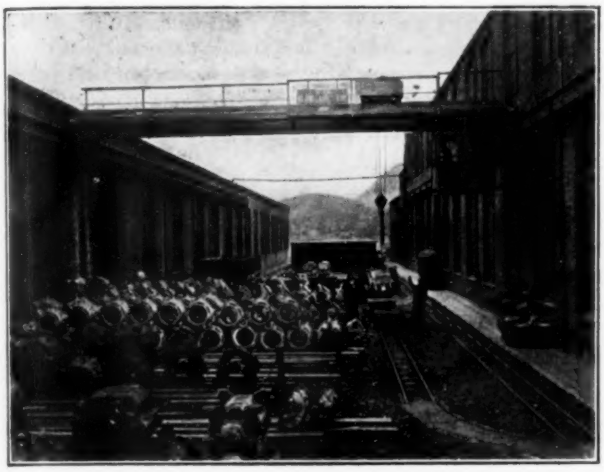

Fig. 3 Outdoor Casting Storage, Showing Materials-Handling Set-Up: Crane Which Can Serve the Standard-Gage Railroad, Industrial Railway, or Industrial Electric Trucks

In some departments it has been found economical to use trailers with trucks, thus doubling or bettering their capacity.

Another truck is fitted as an emergency wiring shop, enabling the wiring-gang quickly to reach and repair any break in the shop electric service.

Trucks collect all wood-scrap, garbage, etc. and take it to the refuse-burning boilers. This work is done at night, the trucks running on scheduled routes covering the whole plant. By doing the work at night, aisle congestion is avoided and better time is made.

Skids, or lifting platforms, are used extensively throughout the works. It was found that the standard skid, designed for the rather narrow platform of the standard electric lift truck, did not permit the handling of large enough loads where bulk rather than weight was the determining factor. So a skid 48 × 54 × $11^1/_2$ in. was adopted as standard, allowing more economical handling of such loads as boxed electrical goods, vacuum tubes, etc. To take care of this size skid, it was necessary to have the truck manufacturers furnish their lift trucks with a platform 40 × 50 in. instead of the 30-in. wide platform which is usually supplied. This size of platform allows the truck to be used as an ordinary platform truck, thereby adding flexibility to its application.

### Incentive Payment Plans

Coordination in itself makes for greater efficiency but at an early stage in the work it was seen that some method of increasing individual effort was necessary. The work was scattered over the whole plant, personal supervision of the foreman in charge was impossible except in a few cases, delays and waits on elevators and cranes were common, and investigation after the delay had occurred was of little use. It was felt that an incentive wage-payment plan placed on the various lines of work would help eliminate delays and stimulate personal effort on the part of transportation men; rather than sit down and wait for a crane lift the truck operator would hunt up a supervisor and insist that his work be taken care of in a reasonable length of time. To establish such a payment plan took considerable investigation and an attempt will now be made to show how a plan was worked for several of these activities.

### Industrial Railway

A survey of the plant was made and conditions affecting industrial-railway work were studied, such as routes to be followed, material handled, frequency of service necessary, and other factors. Routes were then established, taking these points into consideration.

Time studies were then taken over a period of several weeks, securing time values on the getting of loaded cars from the various sections and their disposition, the spotting of empty cars, the time in transit, and the time lost in transit due to various unavoidable delays.

An analysis of these studies showed the following detail operations:

1 Couple and uncouple car (performed twice per car)
2 Switch car (performed twice per car)
3 Deliver car (performed once per car)
4 Allowance for delays (allowed once per car).

The time for each of these detail operations was secured by taking the total detail time of each operation and dividing this by the total number of cars handled during the time of study.

This procedure is repeated for each manufacturing department served by the route.

From past records, the total number of cars handled per day for each section is secured, then by using these figures as a multiplying factor and dividing the sum by the total number of cars handled per day, an average time per car is secured, which is used as the base time for establishing a payment plan on the route studied.

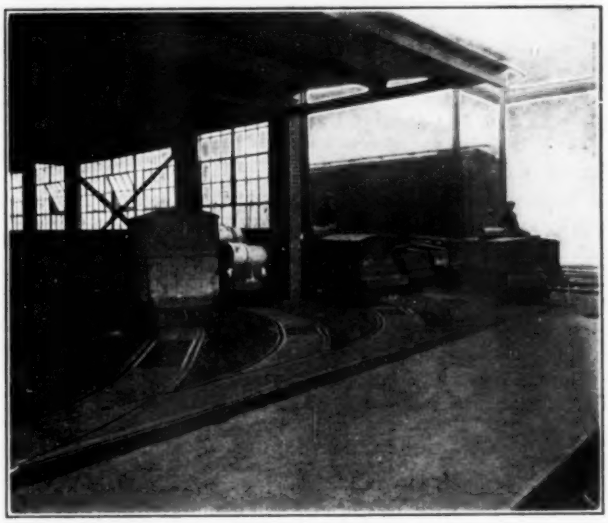

Fig. 4 The Classification Tracks Where Industrial Railway Trains Are Made Up by Yard Crews
(This corresponds to the classification track in any standard-gage railway yard.)

This figure is multiplied by the number of men in a crew (two) in order to secure the time in man-hours.

This is, of course, an average time and if applied to a single car movement would not check, but by using the group system of payment it proves accurate enough for all practical purposes.

In order to secure a check of the number of cars handled, a checker, stationed at the classification shed, keeps a list of the car numbers brought to the shed. This list, in conjunction

with the stubs of the regular car-movement tags which are pulled when the cars are delivered to their destination, gives a record of the number of cars handled and is forwarded to the payroll division as a basis of payment.

### The Group System

A brief explanation of the group system of payment is in order, since this is a part of all transportation payment plans.

A number of men, working on any certain operation or operations, are formed into a group under the leadership of one individual, called the group leader, who is responsible for the planning and direction of the work. The time made by the group is pooled for each pay period and distributed to each workman on the basis of the number of hours worked by each. Allowance for the time taken by the group leader in supervision is made on the basis of the number of workmen in the group.

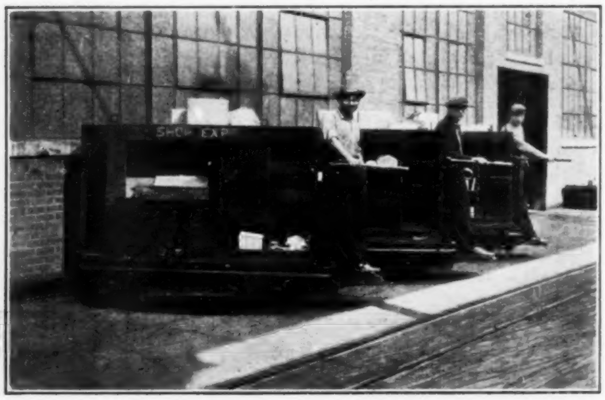

Fig. 5 Carrying Units for the Shop Express
The body design was adopted after considerable experimenting and combines carrying capacity with lightness and strength.)

Under the plan the time values, which are, as explained, necessarily average, can be applied and distributed over a pay period and the individual inequalities are smoothed out.

The group system is peculiarly fitted for transportation and materials-handling work as the members of the group, knowing that their pay depends upon the earnings of the group as a whole, do not hesitate to assist one another and thereby save many delays. If workers are paid on an individual basis, this is not always the case.

### Payment Plan on Industrial Trucking

Placing the industrial trucking on a dispatch system had greatly helped trucking efficiency but a limit seemed to have been reached where further gains to be secured by combining loads, routing of truck trips, use of trailers, and other factors could not be secured. The speed of the trucks was limited but it was felt that if the driver could be encouraged to use greater effort and exercise ingenuity to meet different situations, further economies could be made, so a wage-payment plan was established on this work. This was pioneer work, for although payment plans had been established on other truck work where the routes and work performed were standardized, here was an entirely different problem. Trips were on call, at one time the dispatcher might combine a number of calls into one load, at other times the same route would be covered to fill one call; sometimes trucks were loaded to capacity, at others only a small part of the capacity was used; lift-truck loads were different from platform loads since no loading and unloading time was involved.

The most practical way of basing payment was on the load or call as shown on the dispatcher's board ticket, so the problem was to secure a time value which could be applied to the average load.

Time studies were taken on the work from each manufacturing section served by the dispatch district, which showed the running time, loading time, unloading time, and delays of each type of truck used on the work. From these data, a time value for the average load from each section was secured. The next step was to secure a time value for the average load in the district.

From data secured on the time studies and from past records of the work performed in the district, the number of loads per day from each manufacturing section in the district was secured and this figure used as a multiplier of the time value for the average load. The total divided by the total number of loads gave a time value which could be used as a base time for each load or call on the dispatch board.

This was similar to the plan used on the industrial railway, but the studies disclosed one fact that had to be taken into consideration. That was the number of loads or calls per truck could be increased considerably without proportionate increase in effort on the part of the truck driver. As an example, if the shop was busy and the production load was large, there would be a large number of calls on the dispatch board at one time and the dispatcher would be able to group several loads in one truck trip. The loading and unloading would perhaps require more time and effort on the operator's part but the running time would show little variation, regardless of the load. From an analysis of these time studies and from studies taken over a larger period of time on similar work a multiplying factor was adopted, in this case 0.25, which then gave the true standard time on which payment was made.

As a check on the number of loads hauled, a small slip or "truck service" requisition was adopted. This slip is filled out and signed by the foreman of the section requesting the truck service, showing the section requesting material to be hauled, its destination, and the truck number answering the call. This slip is turned over to the trucker and at the end of his trip is turned in at the dispatch station. The slips are then checked against the call tickets taken from the dispatch board and furnish figures on which the payroll department makes up the pay.

This work is also under the group-system payment plan.

### Shop-Express Payment Plan

The three trucks operated as shop express carriers, as previously mentioned, are also paid on an incentive basis, studied in a similar manner and administered in almost the same way. There are a few additional points in this plan.

As the trucks must run on schedule, each trucker carries a card which is stamped by a time clock at several different points on the route; the payment plan provides a penalty for non-adherence to this schedule.

With such a large number of packages handled in such a short time, there is a possibility that goods will become damaged through hurried or careless handling. The payment plan provides a penalty for such cases.

Delivering to so many different points in the shop, there is a possibility that the driver will make a wrong delivery. The plan also penalizes for such mistakes.

Check on delivery and on quantity is provided for by the "shop express" shipping tag which must be attached to each article. This tag is serially numbered and has a detachable stub, both tag and stub show shipping section, destination, and identification number. Upon delivery of the material at the destination, the driver detaches the stub, stamps the delivery-station number on the back with a rubber stamp located at each station. At the end of the day the stubs are turned in to the works transportation office where they are counted and then filed numerically according to date. This file furnishes a ready reference for

information concerning delivery of any material shipped on the express trucks.

All transportation wage-payment plans involve the group system and the standard-time system of wage payment. These plans have been discussed fully in a paper[2] on "Coordinating Wage Incentives and Production Control" written by D. B. Charters of this Company.

Incentive payment plans are not as yet established on all materials-handling activities, in fact, not much more than a good start has been made, but with the successful installation on the part of the work where it is already used, there is reason to believe that such plans can be worked out for a greater part of the work, and under the direction of the time-study division, arrangements have been made to continue the work as rapidly as conditions permit.

## Economies

The economies resulting from this organization are not all measurable but nevertheless are of considerable benefit and their effect can be easily seen.

One of the gains in the organization as a whole is the fact that all transportation facilities are under one direction, which means that the production or planning department has to deal with but one department, leaving it to this department to move the material in the most efficient manner. If it is necessary to use more than the one transportation medium, transfer arrangements

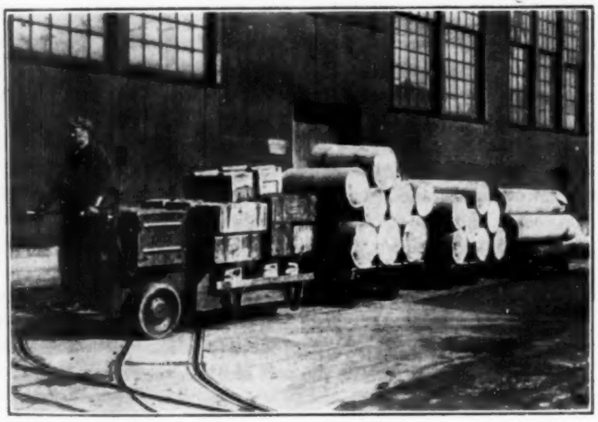

Fig. 6 An Economical Way of Handling Paper Stock (Showing the adaptability and capacity of the lift truck.)

can be made easily without referring to several department heads. As an example, a casting is to be brought from an outside source. This must first be loaded on an automobile truck and brought to the plant, then unloaded from the truck by crane to the industrial railway, and transferred to the section doing the first machining work. Without a central transportation department it would have been necessary for the production supervisor to get in touch with the truck department, the crane department, and finally the industrial-railway department.

In making layouts for new manufacturing sections the layout division needs only to consult with one department in order to arrange for transportation facilities. This also holds true of any other staff activity touching upon or desiring information covering transportation work.

Another economy, part of which can be measured, is that afforded by the installation of the truck-dispatch scheme. This supplanted a method of control in which trucks were assigned to departments under the direction of the individual foreman.

[2] See Trans. A.S.M.E., vol. 50, 1928, paper MAN-50-3.

Hand trucking between departments was practically eliminated because the industrial-truck service was made so readily available that the supervisor used it in preference to hand trucking. Any transportation scheme which does not take this fact into consideration and does not avoid all needless "red tape" can hardly hope to meet with success, for it is only with the full and un-

Fig. 7 An Industrial-Truck Dispatch Station Showing the Dispatch-Board Layout

forced cooperation of every line supervisor that efficiency can be secured. "Service" must be the slogan of a transportation department and this must be expressed in the working of the plan rather than by words.

Another saving is a decrease in accidents, both to workers and to material handled. This work by its very nature is peculiarly subject to such troubles but accidents were reduced and damage to goods in transit lessened mainly by the closer supervision afforded by the plan and the closer check on the work performed, with the opportunity of placing responsibility for accidents on the right party, not losing sight of the fact that with a central organization better opportunity is afforded for teaching safety-first methods and spreading safety-first propaganda.

Another gain was the better care given to equipment and a consequent lessening of maintenance costs as well as an improvement in appearance of the trucks, brought about by the fact that the dispatchers were close enough to the men to teach them pride in the appearance and operation of their trucks.

One way of computing saving caused by the installation of the dispatch plan and the incentive payment plan on the industrial truck work is to figure the number of trucks doing the work at present as compared to the number prior to the plan.

Formerly there were 88 trucks in service, some of these of course in stand-by service. At present there are 67 trucks in active service. Making allowance for six stand-bys in original

service, this shows a saving of 15 trucks. The operating cost of a truck is $130 per month. Subtracting from this saving of $1950 per month, the cost of running the dispatch stations per month, $950, we have a measurable saving of $1000 per month.

On industrial-railway work a similar calculation can be made. With the installation of an incentive payment plan, a reduction of three locomotives and crews was made. The monthly operating cost per locomotive and crew is $500. From the monthly saving of $1500 we subtract $550, the cost of administering and checking the plan, and a net saving of $950 results.

Close check is kept on the production load, and materials-handling facilities are kept in accord with this load. At the same time, check is kept on individual unit efficiencies and progress is being made on handling more material per unit, whether it be the railway or industrial truck. Under individual or sectional control it is hardly possible that materials-handling problems would receive the concentrated study given to it in the centralized department, for the attitude toward such problems would be influenced mostly by the effects on the section interested, while the effect on the plant as a whole would receive little consideration.

The organization as outlined is not a panacea for all materials-handling ills, nor is there any assurance that it is one which will take care of the problems of the future, but after trials of various methods of materials-handling control by the Westinghouse Electric & Manufacturing Company, it is believed that this more nearly meets their present-day requirements and shows better results than any other plan which has been offered.

## Discussion

G. H. Ashman.[3] Transportation at the General Electric plant follows rather different lines, although it is similar in some respects. All cranes and elevators, their maintenance, and their operators are under the control of one supervisor who has no connection with production work. Their movements, however, are entirely under the direction of the shop or section in which they are located. That applies also to yard cranes and all internal transportation. A separate transportation department has charge of the movement of all material outside of shop buildings, four distinct methods of transportation being in use: (1) standard-gage railroad, (2) narrow-gage railroad, (3) trucks, and (4) tractors and trailers.

Included in the equipment of the standard-gage railroad are two 75-ton and five 50-ton electric locomotives. The narrow-gage road employs ten locomotives, ranging from 30 tons down to 10 tons. There are 650 narrow-gage cars available.

The industrial trucks are 67 in number, ranging from $^1/_2$ ton to 5 tons. Of these 60 are electric and the rest are gas trucks.

A new system of tractor and trailer transportation has just been inaugurated, and while still in its infancy, the results indicate that it will be most economical. At the present it consists of 7 tractors and 250 trailers. In addition there are 46 passenger automobiles for official use, 7 of them with regular chauffeurs. Three electric buses operated on a regular schedule are run from one end of the plant to the other. The longest freight haul is about $1^1/_2$ miles, with the average around three-quarters of that. Approximately 6,500,000 sq. ft. of manufacturing and storage area must be collected from. This is a little more than the space noted by the author.

The standard-gage road handles the incoming and outgoing freight, also transporting the bulky material from one department to another. This operation is through a regular dispatching force of 11 men. There is a yard master, an assistant yard master, a night yard master, and a route manager. All have automobiles for keeping in touch with the crews in different parts of the yard.

All requests for transportation are forwarded by telephone to the dispatcher's office. A dispatch sheet is used rather than a dispatch board such as the author describes. The request is entered at the time of its receipt. Duplicate orders for the delivery of material are issued, on which are given the time the order is received, description of material, and destination. One copy is sent by mail to the man requesting the delivery, and the other is handed to the crew. Those two copies must check one against the other. This system applies to the standard-gage, narrow-gage, and to trucking, but not to the tractor-trailer system.

The tractor and trailer service is a new and interesting development, flexible and instantly adaptable to sudden changes in routing. This plant is divided into five zones, each zone being tended with a separate shuttle service. Every department in each of these shuttle-service zones has its own platform to which material, either in package or carload lots, is delivered and from which collections are made by the shuttle tractor. Located in the middle of the plant is a classification yard, and shuttle tractors deliver to and receive their trailers from this central point.

Both gas and electric tractors are being used, and also a gas-electric type in which the power plant, consisting of a gas-electric generator, has been adapted to fit in the battery compartment of a standard battery truck. With this latter, maximum power is at all times available, with no loss of tractor effort due to partly discharged batteries.

The group or premium plan of wage payment is not used, operators at present being paid straight day work. The cost of deliveries is computed from the completed trip, a completed trip being delivery of the empty car or the empty trailer for loading and its delivery to destination when loaded.

The cost of a complete trip on the standard-gage averages $3.50 and for the narrow-gage about $1.15, these figures of course including all overhead expenses. For the tractor-trailer system the cost is only about 36 cents. The cost of operating the truck as given by the author, seems exceptionally low. From records of operation with which the writer is familiar, with two men to a crew, labor alone would amount to about $220. The gas consumption of a truck averaging 775 miles per month costs around $22, and the average repairs, including tires, amount to about $35. The writer cannot see how the cost of $130, as given in the paper, was attained.

William Elmer.[4] The writer was recently astonished to learn in a conversation with a representative of the Department of Commerce that the total bill for materials handling in this country for 1926 amounted to four billion dollars. That includes the large unit carloads of coal, ore, etc. which are handled over dumping machines, but when we segregate the cost of handling materials carried in small lots, there are various estimates, but the figures approximate a billion dollars a year. This is subject to a considerable reduction by the use of such methods of transportation as have been developed by the author of this paper.

The individual studies in certain plants have shown savings of as high as 90 per cent in the cost of handling materials. Those figures seem almost impossible, yet when the details have been studied both before and after the introduction of improved methods they check. Assuming that such a figure as 50 per cent is realizable, one can see that there is a mark worth shooting at—a saving of half a billion dollars a year in the materials handling of this country. Suppose that 50 per cent is too great; halve it, and there is still a quarter of a billion dollar saving.

The individual skid mentioned in the paper was selected on the

[3] General Electric Company, Schenectady, N. Y.

[4] Special Engineer, Pennsylvania Railroad Co., Philadelphia, Pa. Mem. A.S.M.E.

basis of experience. There are various types of manufactured skids as well as the home-made variety which are in use to the extent of hundreds of thousands.

One of the largest manufacturers of trucks has said that he would willingly scrap all their dies, patterns, and materials if a standard skid or a few standard sizes could be agreed upon. Since a great deal of future freight movement will be made by standard-gage railway cars, it is evidently quite desirable to select a type of skid which can be used satisfactorily in box-car shipments, the idea being that when the material is shipped it can be loaded on skids.

On reaching its destination it would be handled by the receiver's skid trucks. If a skid can be chosen which will pack into freight cars and allow the loads to be properly wedged and set for transportation so that the shocks of handling cars and railroad service will not damage the goods, undoubtedly large sums of money can be saved.

H. P. Reid.[5] One of the greatest problems of a standardization program lies in the great difficulty in meeting the different floor levels, the car-door size, the car size, and the eaves height. The floor levels constitute a great difficulty in the perfection of any kind of a standard box-car loader.

The product of the writer's company goes out entirely weighing 95 lb. These sacks are loaded from 500 to 1200 or 1300 sacks per carload, which means stacking from four high in the larger loads. Many attempts have been made to develop a car loader for such packages, but thus far none has proved satisfactory, so far as the writer has been able to determine.

Up until a year or two ago a standard box car was used by the writer's company for the transportation of empties from the recovery and reclamation departments back to the packing department. It was found after a careful study that the time cost could be greatly reduced and the different stations supplied much more satisfactorily with empties by the use of an auto truck of special design. The loading stations for these empties are such that three different auto-loading platforms must be used. The distribution stations for this auto truck are 11 in one plant and are so scattered as to require trips for the auto truck of from a few hundred feet to half a mile. To cover this area with a sort of transportation system, from four to eight railroad switching tracks must be crossed.

An automobile truck with a lifting body to take care of the deflection of the springs as the load is applied was developed. This special-bodied truck with the use of platform trucks on caster wheels has reduced the costs of handling of empties about 50 per cent. The system paid for itself within twelve months.

This company uses special-size platform trucks employing two rigid and two castering wheels. For this service the wheel-mounted platforms have been found far superior to the skids and lift truck. The returned empties are kept on wheels from the time they are received and unloaded from the railroad cars or from automobile trucks until they go into storage, and as they are taken out again, they are again kept on wheels until they have been filled at the packing plant.

It has also been necessary to develop a special-width platform truck for unloading cars. It was found possible to build a truck which would handle roughly 2 tons on four wheels, using aluminum instead of rubber tires, and one handled by two men which could be run into the box car, so that receipts from different shippers when mixed in the railroad car could be sorted, and the movement of these sorted shipments was much easier and speedier than could be accomplished with skids.

The experience of the writer's company with lift trucks has been that the floors and runways have to be comparatively level to permit their operation. They cannot take care of heavy deflections in the floor nor turn corners readily on inclines, as for instance from the unloading platform to car-floor levels.

G. F. Tegan.[6] At the Swissvale plant of the Union Switch and Signal Company the coke formerly was brought in box cars and unloaded in the orthodox fashion, that is, by wheelbarrows, shovels, etc. The limestone was handled in much the same way, and the pig iron and scrap were handled in open-top cars with a magnetic crane.

Lately there have been certain changes in handling methods. Bins were built in the ground, and a trestle was erected for handling the coke and limestone. The old track was used for unloading the pig iron and scrap, which is dropped. As a result of those improvements, the superintendent of that plant said that they had reduced their man-hours from 49 to 22 and had cut the total cost of handling materials in their foundry practically two-thirds.

P. W. Power.[7] Owing to the writer's work at the Pittsfield plant of the General Electric Company in connection with the provision and use of equipment, there are points in this paper that are of special interest in connection with that work.

Owing to the location, the long winters with accompanying snow and ice made the elimination of the narrow-gage track desirable. The substitution of tractors and trailers has proved to be of great advantage, since the cost of clearing snow and ice out of the grooves of the rails sometimes amounted to more than the trucking costs.

Another point worthy of mention in connection with transportation by means of tractors and trailers is that a good runway or roadway is quite necessary to complete success. In the case of the Pittsfield plant, paving extensions of either concrete or brick, both outside and in the shops, made corresponding reductions in costs of maintenance of floors and roadways and the ability to carry heavier loads and carry as high as 8 tons. The problem in this case is to get good wheels. Iron- and steel-tired wheels were used in the beginning, but it was found that wheels would occasionally break, and also they would damage the floors.

Metal tires have been abandoned in favor of rubber tires, and little by little the quality of these has improved until now experiments with a recent type indicate that soon we shall have rubber tires that will withstand greater traffic over greasy and oily floors.

When the more extensive use of tractors, trailers, and trucks was inaugurated at the Pittsfield plant seven or eight years ago, it was not so easy as it now is to purchase satisfactory trailers. Some were made at the plant and others were purchased. A good deal of expense was required for maintenance, for the bearings particularly.

The millwright department always had two or three trailers under repair. Roller bearings of the spiral-wound type were tried. Their use has been extended until for the past three and one-half years no other type of bearing has been employed. A recent check-up of these bearings on 600 trailers in use disclosed the fact that to date no money has been spent on maintenance, repairs, or renewals.

The matter of skids has been referred to. The writer would be very glad indeed to find and use the standard skid that may be adopted. A large sum has been spent in making skids, both platform and box types. They are expensive to use and maintain, and it seems that if a standard size was produced it would be of very great value and very good for interchangeable service.

[5] Universal Portland Cement Co., 210 South La Salle Street, Chicago, Ill.

[6] Editorial Representative, *Iron Age*, in Pittsburgh, Pa.

[7] Mechanical Engineer, General Electric Co., Pittsfield, Mass. Mem. A.S.M.E.

The writer would like to obtain information on a good method of handling copper wire on reels weighing 250 lb. each. The damage and the wear and tear to reels are very high, and a really good method of handling does not seem to be available. Perhaps the author can enlighten us.

Charles C. Leeds.[8] It would be interesting to know if a study has been made as to the relative cost of electric versus gasoline trucks, and if so, what results were obtained. The speaker would also be interested to know if the system worked out by the Westinghouse Company does not require a rather elaborate clerical force to handle the system, forms and checking, etc.

Charles B. Patt.[9] It would be helpful if the author in his closure would explain whether the transportation department has charge of the upkeep of all the transportation facilities including the elevators and cranes, trucks, tractors, and so forth, or whether it comes under the head of the mechanical division and they simply look after the operation.

### Author's Closure

The author's paper handled the problem from the standpoint of management; that is, organization and control. The discussion brought out by the several people is not from exactly the same angle. However, various points are brought out that perhaps can be answered.

Mr. Reid's experience with lift trucks and skids closely coincides with our own, and our conclusions are the same.

We can understand Mr. Power's difficulty with industrial railway installation. In our East Pittsburgh plant we do not have so much difficulty with snow removal as the tracks are laid on ties in line with standard-gage railroad practice in nearly every case where the installation is outside of the buildings. For this reason we have not seen fit to supplant the industrial railway with tractor and trailer, although there are some places where trailers are used to a considerable extent in conjunction with the electric industrial trucks.

Our experience with wheels and bearings is the same as that given by Mr. Power; that is, we found that the rubber tires are the best and the use of the roller bearings has eliminated our trouble in that respect.

We are unable to furnish much help in Mr. Power's inquiry concerning the proper method of handling copper wire on reels. We use a sling for handling by crane to the trucks or cars and unload by hand, using a "beer mat" to break the force of the contact and eliminate reel breakage. We know this is not a very good plan, but it is the best of which we have been able to secure any knowledge.

[8] Carnegie Institute of Technology, Pittsburgh, Pa.

[9] American Steel & Wire Co., Pittsburgh, Pa.

Mr. Elmer brings out some very interesting points concerning skids, and we agree that it would be of greater advantage to have standard skids and make shipment of material between supplier and consumer by means of skids which would fit on standard-gage railroad cars. I believe there has been some progress made in this respect with sheet steel in some of the automobile plants, and recently we have been spending some time in research on this same question.

Mr. Leeds makes an inquiry concerning electric versus gasoline trucks. We presume that he means trucks built for outside road service. We have made some studies and accumulated some data on this, and we find that if conditions are suitable for the use of an electric truck—that is, short hauling with fairly level roads—comparison is in favor of the electric truck. Under other conditions—that is, long hauling, infrequent stops, and hilly roads—the gasoline truck is the more economical. It may be that Mr. Leeds refers to the gas-electric industrial truck which has been mentioned by Mr. Ashman. In this case we have not accumulated any data, but our studies again show in favor of the electric truck, basing our conclusions on the cost of operation of a gasoline truck compared to that of an electric truck. No doubt there are exceptions to this conclusion, one of which would be if charging power was not readily available.

Regarding the clerical force which is needed to handle the organization and about which inquiry is made by Mr. Leeds, I would say that the clerical force is smaller than under any former organization. One clerk takes care of the forms and checking, with the part time of two other clerks who assist in taking care of the wage-payment plans. This of course is in addition to the regular supervisory force of the organization.

Mr. Patt inquires concerning the upkeep of the transportation facilities. Within the plant transportation organization we have one department designated as the transportation maintenance department which takes care of the maintenance and upkeep of all transportation equipment with the exception of cranes and elevators, which owing to their complicated nature, involving both mechanical and electrical repair work, are taken care of by a separate department. The operation of cranes and elevators is directly controlled by the manufacturing departments in which they are located, and responsibility for their proper operation and maintenance is located in this other department. This will also answer the question brought out by Mr. Ashman. The cost figure which Mr. Ashman brings out and which he questions in our case is the figure for an electric industrial truck. The figure which he uses as a comparison is, I believe, a gasoline road truck, which of course would not check with ours. Our gasoline road truck costs are based on the cost per mile, which varies according to the capacity of the truck. A $3^1/_2$-ton truck costs about 50 cents per mile, including overhead, depreciation, and all other factors.

MH-50-9

# Handling Methods and Equipment in a Large Mail-Order House

By H. E. ODENATH,[1] PHILADELPHIA, PA.

In production by modern handling methods each type or kind of industry has a specific object it desires to attain by installing such methods. In many industries the main object is reduction of cost by eliminating waste motion or hand labor. With a large mail-order house, more than in any other industry, the chief object is time. Speed is an essential in handling the orders, as it helps to make and to keep the good will of customers.

Next to the time element must be reliability of equipment. Supervision and inspection enter prominently into this, for breakdowns are always disastrous.

As with all continuous-flow materials-handling systems once it is in satisfactory operation it becomes a medium for excellent production control and timing of production; so that with our present system of handling orders, which is a development of many years, we need only to put a satisfactory timing on each operation of each order to secure a successful continuous flow of filled orders.

Before going through the layout of production, it might be helpful to outline our problems. In developing this system we are faced with the necessity of handling as high as 50,000 individual orders a day. These vary from trifles such as toothpicks and handkerchiefs to stoves, rugs, and farming implements. Some orders are filled in one merchandise department, while others must be filled by contributions from many widely separated departments.

This makes it necessary to have not only a system of handling the merchandise but to have a reliable system of handling the invoices to different departments, with rapid methods of indexing, filing, recording cash, separating orders for the departments, and timing completion of orders.

The first part of our systems may be described as mass production of bookkeeping, indexing, filing, cashiering, and scheduling, and the second part as mass production of picking goods, assembling, wrapping, weighing, and stamping of merchandise to thousands of customers.

From the layout of our plant (Fig. 1) the flow of orders can be followed. Our mail truck picks up at the North Philadelphia post office the first morning mail and delivers it to the sixth floor of the office building, where the pouches before being opened are thrown on the scale and the net weight of all mail determined for this trip. From this weight our managers are able to approximate the volume of business for the day, and the pressure of the work schedule is arranged accordingly.

The operators open this mail at the rate of 400 to 500 pieces a minute with an electric slicing machine that cuts the envelopes without mutilating the contents. The orders are pinned to a temporary file back, and the amount of the cash or check enclosed is entered in pencil on the face of the order. The cash is counted in a division of the cashier's office on the left, and the orders after being balanced with the cash are placed on a belt. From this point the orders are delivered through a gravity chute to the entry department on the floor below.

When a customer's orders must be filled from two or more departments, the items must be separated, and that is done in the entry department. An invoice is made for each department represented on the order, and the completed invoices and the original order are pinned and placed on the moving belt. There are four such belts in this room for conveying the mail to the rear of the room.

As was done on the sixth floor, this department also dispatches its finished work through the chute to the floor below, which is the general index department, with a capacity for holding and recording the accounts of 3,000,000 customers. As the orders arrive from the fifth floor they are handed to the operators who sit at the beginning of these belt conveyors. These look like long channels, as there are partitions between the six 2-in. leather belts (Fig. 2), the longest of these runs to the end of the room and the shortest to the first aisle. The orders are sorted alphabetically, and they are then routed by the belts to the proper sections of the department. Those beginning with A, B, and C

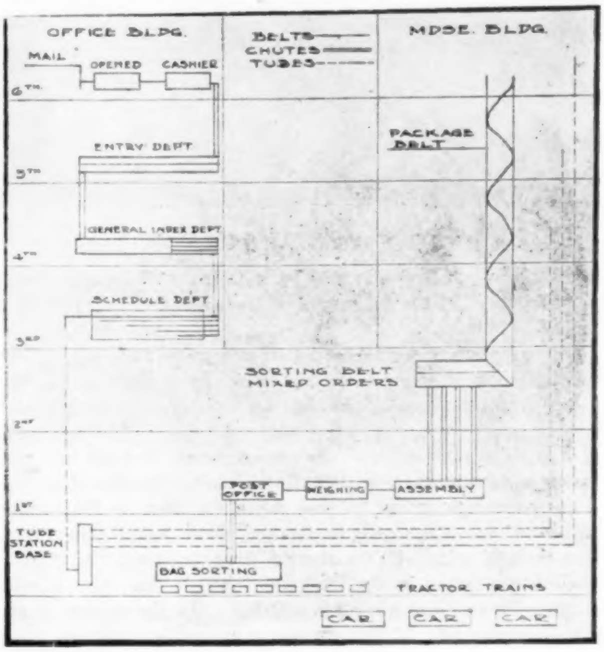

Fig. 1 Routing of Orders

go to one station, D and E to another, and so on. The index is arranged by towns in alphabetic order. This is done to avoid the congestion that would result if a geographic division by states and counties and towns was used, as business from one section of our territory is sometimes heavier than from others.

At every row of file cabinets is a station for further sorting the orders. There are six or seven of these stations. From here the orders are delivered by messenger to the operators in that row. The belts merely deliver the orders to the different stations. The file cabinets are placed back to back against the belts which carry the completed work to the rear of this room. These belts discharge on one high-speed belt underneath the platform.

The completed work leaves the department through a chute that discharges on the floor below in the scheduling department. In this room are addressograph machines, the address plates of

[1] Chief Engineer, Sears, Roebuck & Co. Mem. A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Materials Handling Division, Philadelphia, Pa., April 23 and 24, 1928.

each corresponding with one section of the shipping room. There the several invoices for each order are stamped with the same schedule. This consists of the shipping-room division, section, and basket numbers and the time due. The time for each shipping-room section is changed every ten minutes. This avoids

FIG. 2 DISTRIBUTING ORDERS BY BELTS

duplication and provides for an automatic distribution and control of work. In the technique of the store this referred to as "schedule."

The invoices are sorted by departments and time into a long row of bins which form a sorting rack. From here on they are called tickets and are dispatched to the different merchandise departments by a system of pneumatic tubes. The bins hold tube carriers stenciled for the departments, and on the rails above the bins are narrow belts which convey the closed carriers to the pneumatic tubes. These tubes are used in dispatching mail from one department to another, there being three trunk lines each of which serves several departments. The regular schedule on orders is also handled through this tube system, making it possible to work our schedule. In the course of one day approximately 25,500 carriers are handled through these stations.

In the pneumatic tube relay, station boys transfer the carriers from one line to another for delivery to the merchandise departments, where the orders are priced and the sales are listed. After the orders clear the ticket office the merchandise is picked up and carried to the rechecking and wrapping table (Fig. 3) and given a protective wrapping, and then is placed on a conveyor which discharges to a spiral chute which delivers on belts in the sorting department (Fig. 4) on the second floor of the merchandise building. This department receives, sorts, and distributes the mixed merchandise to the assembly room below. "Mixed merchandise" is an order that must be filled from more than one department. This merchandise is received in the sorting department from the merchandise departments on a 10-min. schedule. It is permissible for departments to send their merchandise 25 min. before schedule, but not a minute later, under the penalty of being charged 50 cents for each piece received late. This charge is credited to the shipping room and is deducted from the department charged. In sending merchandise 25 min. ahead of schedule the sorting department is enabled to sort three schedules at one time from the primary or sorting belt. In the secondary sorting two schedules are sorted at one time according to sections and distributed over conveyors to those sections, the last order being released to the assembly room of sections 15 min. after the schedule is sorted.

In the assembling room the orders are checked in canvas baskets according to schedule on order. When complete, the orders are packed and sent over conveying belts to the weighing division. Orders that are not completed on time because the merchandise was received too late or for some other irregularity are held for one hour, and then if not completed, they are sent as they are, and a second shipment is made later and the charges prorated.

In the weighing division (Fig. 5) all parcel-post shipments are received over a conveying belt and are cleared from the tables on either side once every hour to the post office on the same floor. The mode of distribution to the post office is also by conveyors.

Here the postage is affixed by weighers who use computing scales. The packages are received on the 48-in. belt conveyor, which passes through a movable distributing carriage. The belt as it reaches the carriage turns back over a roller, and then passing around a second roller goes underneath the carriage. This distributing carriage (shown in Fig. 5, upper center) travels back and forth the length of the scale tables, while the belt moves forward and drops the packages to a short transverse belt mounted on the traveling carriage and moving up and down the aisle with it. This transverse belt is reversible so as to discharge to the scale tables on either side.

Single orders, or orders filled in one department, are picked, checked, and packed by the department receiving them and sent

FIG. 3 TYPICAL WRAPPING DEPARTMENT WITH CONVEYOR

to the weighing division over conveyors without going through the sorting and assembling processes of the mixed orders.

Freight and express orders average only 5 per cent of all orders received, and are therefore handled on a smaller and different scale.

The operatives in the post-office division are employees of the Government. The outgoing mail is sorted into pouches ac-

cording to towns and states. There are five conveyors between the floor and ceiling directly over each other. Adjacent to these belts are the operating galleries where the mail is sorted.

The post office uses 3110 sacks to make this separation. The mail sacks are lettered, and when full they are tied and locked and then placed on conveyors for the sorting platforms in the basement, where they are sorted for the railway mail cars, which also are designated by letters. The men in the basement place these sacks in trucks destined for the platform of the individual cars. These trucks are made up into trains so that they may be tractored out in the order in which the cars are spotted on the tracks and are then unloaded into the cars. This separation by number and position, as laid out by the post office, enables the clerk who works in a particular car to dispatch all mail as it reaches its destination. In this mail handling we average about 9000 sacks daily, and during the holiday season we have reached a peak of 25,703 sacks. Our average number of mail cars is 23, and for a peak day, 35 cars. At such a time we are required to make two shifts in the switching of our mail cars. Our platform space enables us to spot 45 regular box cars. We unload about 35 cars per day of incoming merchandise. We load 15 to 17 cars of outbound freight, using the box cars unloaded.

In the unloading of inbound merchandise on straight carloads it is placed on departmental trucks set on the platform with one end against the side of the car. The car checker attaches tags to these trucks showing the quantity and catalog number, truck number, and the car from which this merchandise is unloaded. This tag is taken from the truck by the man receiving and piling this merchandise in a department, who verifies the quantity as he puts it in stock. This is used for our check, and the quantities taken from these tags are entered on tally sheet.

The forwarding of the merchandise from the cars to the different departments is done by truckers who make up train loads from the cars to the various elevators.

## Discussion

### Author's Closure

S. D. Graff[2] asks what percentage of time is required for handling the order.

B. A. Hildebrant[3] asks about the time. The merchandise departments are allowed 2 hours and 10 minutes before the schedule is due. The shipping rooms are allowed 1 hour and 15 minutes. As to the red and blue colors, the red label is used for parcel post and the blue for first-class mail; a stamping machine is used, but for parcel-post work precanceled stamps are dampened on a sponge and stuck on the package.

A. F. Mojesctic[4] asks about the penalties. The departments may send packages to the sorting department 25 min. ahead of schedule but no sooner, because the sorters have time only for three 10-minute sortings. A penalty for a "late" is charged to the department making the error, and the shipping department gets the 50 cents credit because of the separate handling and ticket.

[4] Cleveland Tram Rail Co., Cleveland, Ohio.

As to M. Lee's[5] question on the maintenance of equipment, when we started in Philadelphia eight years ago we had 46 conveyors and now we have 110. When we first started we had four men oiling and on general maintenance work and cleaning the motors, and we now have only two men to look after them. I give the credit mostly to the fact that we have almost entirely equipped the main bearings with ball bearings. We have had savings as high as 57 per cent in the power consumption. The maintenance cost for the system of belt conveyors is $300 to $350 a month. The capital investment is $1000 to $1200 each.

Prof. George W. Kelsey[6] asks as to the weighing of mail in the morning as a guide for laying out the day's work schedules. None of the mail is opened to see if it is an order or a complaint or is general correspondence.

The plan has been worked out over a period of years on the law of averages, and it holds good to very close accuracy. They simply weigh a sack full of mail, and from that they can judge within a very few dollars the amount of money and very close to the number of orders.

[5] Eastman Kodak Co., Rochester, N. Y.

[6] Assistant Professor, Industrial Extension Division, Rutgers University, New Brunswick, N. J. Jun. A.S.M.E.

After the mail is opened the longhand letters are typewritten.

As to whether stock is carried in a filling or retail department, in some sections there are storage stocks and in others the stock is carried on the same floor so that moving it into the open stock requires a travel of only 50 to 100 ft. Where a very large stock is needed it will be stored in the nearest space to the department using that merchandise.

Such a thing as "hand handling" could not be done on the scale we do things. From the start the handling by machinery was one of the first things arranged.

Materials coming in from a car are loaded on trucks, run on the elevators, delivered to the merchandise departments, and stored by lifting machines.

Wooden shelving is used in the storerooms because departments are moved quite frequently, sometimes over a week end. Wood is more adaptable, and these quick changes could not be made with steel. The time in cutting down and reassembling would be too much. The wooden shelf units are of the same size, width, and depth, consequently they are adaptable to any department.

The handling of 25,000 orders a day requires an accurate shipping schedule.

# Modern Handling in Enameling Work

BY E. D. SMITH,[1] DAYTON, OHIO

STUDIES of rearrangement plans of the enameling or finishing department of The National Cash Register Co., Dayton, Ohio, were made having in mind the following reasons for such rearrangement:

1 Increased capacity was needed
2 To provide this capacity with existing methods demanded additional floor space which was not available
3 Lower departmental cost, as always, was desirable.

### GENERAL

In an effort to meet the demands as above indicated a careful study of the department was made to see whether it could be changed over from the hand- or push-truck method of handling to perhaps a somewhat modified system of continuous-flow manufacture. The study very early indicated that a large portion of the labor expense was occasioned by numerous handlings. (Figs. 1 and 2.) The nature of the product to be handled was such that handlings must be carefully, even if expensively, made. It was therefore quite obvious that a reduction in the number of handlings was not only desirable from a quality standpoint but should offer substantial savings. After completion of rather extensive time studies an experimental installation was made in order to answer, at least in part, the following questions:

(1) Could the cabinet parts be successfully sprayed with both ground coat and lacquer while in motion?
(2) Could parts be suspended from chains in sufficient number to secure desired output?
(3) Could the vapor and fumes from spray guns be removed in such a manner as to not interfere with the operators' efficiency or health?

### EXPERIMENTAL INSTALLATION

Very few demonstrations were necessary to prove that the spraying could be done while material was in motion. The question of securing sufficient capacity on a chain moving past the operator at a satisfactory rate presented a very considerable problem. There were hundreds of different kinds of pieces varying in size and shape from a half-dollar to complete cabinets not unlike a small trunk. (See Fig. 3.) This was a problem that could only be solved by actual experiment, and a great many different kinds of hangers or trees were tried out. By the process of elimination and change the number of hangers required was finally reduced to nine. These were very simple and inexpensive to make. (See Fig. 4.)

### SPRAY BOOTHS

The removal of vapor and fumes was purely a question of moving the air past the part being sprayed with sufficient rapidity to prevent fumes or vapor from flying back into the operator's face. Spray booths were installed in separate rooms. A slight static pressure is maintained in these rooms by delivery of filtered and tempered air from a fan system. The delivery of air to the room is about 25 per cent in excess of that removed by the suction system. This produces very satisfactory conditions, and there are no complaints from the operators because of air conditions.

In order to prevent drafts or air blasts, the discharge ends of air supply ducts in spray rooms were covered with a very large area of fine-mesh bag similar to those on a standard vacuum cleaner. These are to be seen in Fig. 5.

### BURN-OFF OVEN

In lieu of the washing system formerly used, a burn-off oven was provided. (See Fig. 6.) Parts pass through this oven on a wire belt and are subjected to a temperature of 1000 deg. fahr. for about four minutes. This removes in a very satisfactory manner all the oil, grease, dust, etc. which naturally accumulates during shop handling and fabrication.

The present operations or processes in enameling are as follows:

(a) Clean in burn-off oven
(b) Spray with first ground-coat color
(c) Bake ninety minutes at 230 deg. fahr.

[1] Maintenance Engineer, The National Cash Register Co. Mem. A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Materials Handling Division, Philadelphia, Pa., April 23 to 24, 1928.

(*d*) Putty where necessary to get perfectly smooth surface
(*e*) Spray with second ground-coat color
(*f*) Bake ninety minutes at 230 deg. fahr.
(*g*) Sand for smoothness
(*h*) Grain to produce natural-wood appearance
(*i*) Bake ninety minutes at 230 deg. fahr.
(*j*) Spray with first coat of lacquer
(*k*) Bake forty-five minutes at 110 deg. fahr.

Fig. 3 Showing Parts Making Up a Complete Cabinet
(Note variation in size and shape.)

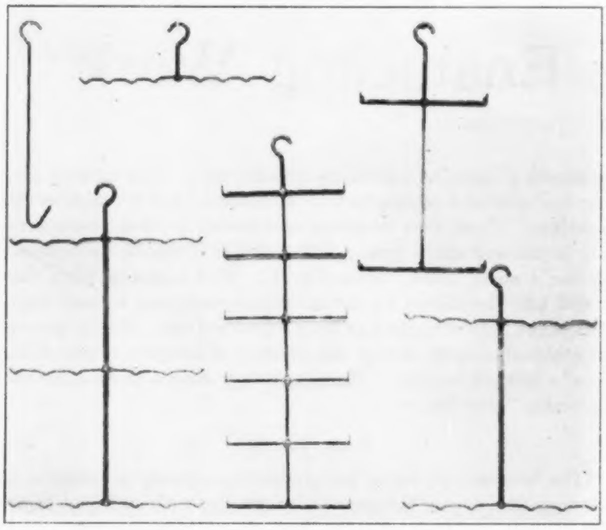

Fig. 4 Showing Six of Nine Standard Hangers in Use

(*l*) Spray with second coat of lacquer
(*m*) Bake forty-five minutes at 110 deg. fahr.
(*n*) Rub.

In passing through these fourteen operations or processes the work is removed from the chain but four times.

### Vertical Movement—Basement to Fourth Floor

The raw-stock storeroom is in the basement and the enameling department is on the fourth floor, therefore economical and continuous movement of stock between these floors was an important part of the scheme. This was very satisfactorily worked out by installing a series or ramps or risers in chains. (See Fig. 7.) The maximum obtainable angle of rise was 20 deg. so that to travel the necessary vertical distance of 51 ft. it was necessary to use 14 risers. As the finished-stock room was also in the basement, the same scheme of delivery from fourth floor to basement was used.

### Ovens

All ovens except those at high temperature for special finish are heated by air passed over steam coils. With the continuous type of oven, such as used, the cubic content was necessarily large and in order to make up for losses and to bring incoming material up to temperature promptly a large number of air changes were required. In the case of ground-coat oven this amounts to 31 per hour.

### Results

The whole installation has worked out very satisfactorily, resulting in savings as listed below:

(1) Annual payroll reduced $59,000
(2) Maximum daily output increased from 600 to 800 units
(3) Floor space reduced 10,000 sq. ft.
(4) Number of handlings reduced from 58 to 20
(5) Improved quality of production due to decreased handling and improved banking conditions
(6) Departmental turn over time reduced from $7^1/_2$ to $1^1/_2$ days.
(7) Reduction of inventory of cabinets and parts 80 per cent.

## Discussion

J. B. Webb.[2] The type of conveyor described is a good illustration of the flow idea in manufacturing: that is, to keep the product

[2] President, J. B. Webb Co., Detroit, Mich. Mem A.S.M.E.

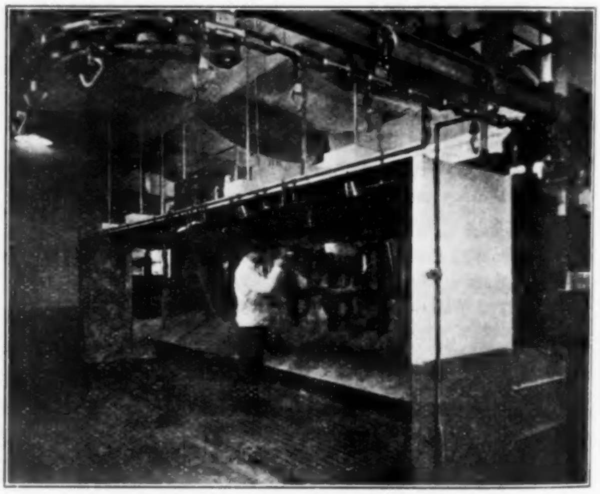

Fig. 5 View Showing Operator at Work in Spray Booth and Air-Diffusing Bags

Fig. 6 Discharge End of Burn-Off Oven

moving. A great many industries are beginning to think about this now more than ever. Credit can be given to the automotive industries for realizing its value to the fullest extent. The minute any labor is performed on a piece of goods, it must be put on the move and sent on to the consumer so that the money for it can be returned as soon as possible and that inventories can be reduced.

There is another factor of primary importance, in fact, of greatest importance, and that is that the flow idea in conveyors means pace making. The work is brought to a man at a definite rate of speed, and is taken away from him at a definite time; he has just so much time to perform his work, and he will do it and consistently keep doing it, while if the time is optional with him he always takes more time than is necessary.

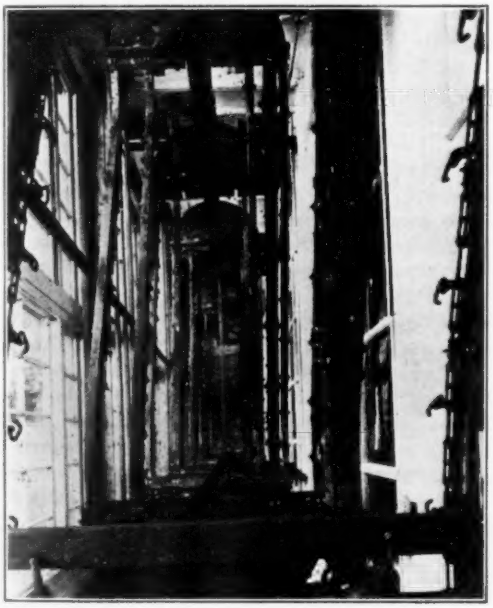

Fig. 7 Looking Down From Fifth Floor Showing Series of Ramps or Risers in Conveyor

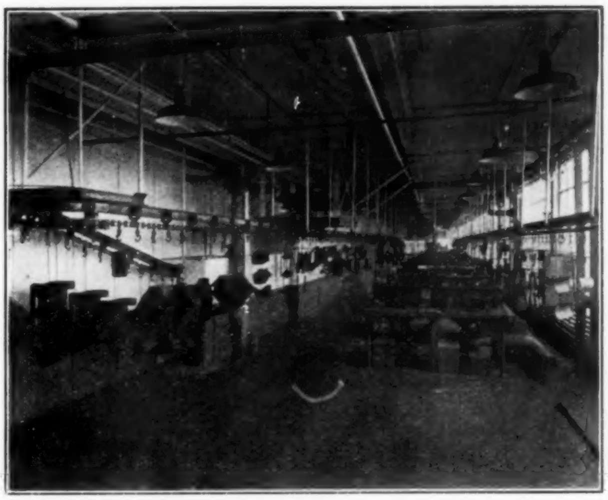

Fig. 8 General View Showing Cabinets Leaving Oven and Sanding Section

I know from practical experience that where work of an assembling nature has been done so that one man performing an operation passes the piece on to the next one, astonishing increases in production have been effected by placing that work on a moving system so the man's time for doing the operation is in the hands of the management and not in the hands of the man himself.

## Author's Closure

In answer to several questions, I would say that the drives of the conveyors are all variable in speed. The predetermined speed by calculation was $7^1/_2$ ft. per min. and we have adhered very closely to that.

As to the relief of operators, we use a handy man who keeps the operators supplied with material and gives them relief when necessary, helps to clean up booths, and so on. We do not have extra operators. We have to have this man anyhow.

We have very few rejections with this scheme now. Rejected pieces are usually laid aside and orders are telephoned to finish another similar piece and send it through.

# Marine Terminal Operation

BY WILLARD C. BRINTON,[1] NEW YORK, N. Y.

THE function of a ship is the transportation of passengers or freight between port cities. When a ship is in port it is not functioning.

For a steamship line in foreign trade or intercoastal work, approximately one-half of the budget is spent on terminal activities. The per diem charges for a ship can easily be segregated in proportion to the number of days the ship is at sea and the number of days in port. Interest on capital, depreciation, and obsolescence can quite readily be allocated. General administrated expenses may not be quite so simple to divide between operations at sea and port activities, but on any basis a large portion of administrative expense is properly charged to the ship in port.

The author would like to publish percentages of representative steamship lines in support of the point of view that terminal activities are such a large fraction of the total budget; however, the confidential nature of these figures makes it difficult to give actual data, and tabulations are therefore omitted.

The maintenance of continuous service of a foreign or intercoastal shipping line requires a number of ships. Operations are naturally on a large scale, and the annual budget of such a line runs into millions. It is surprising that the organization heads of steamship companies usually disregard the functional division between port activities and sea activities. They handle their port activities on a basis of line organization rather than of staff organization. The executive at the top whose scope is sufficiently wide to include all port activities is busied with many and varied problems affecting his corporation as a whole. There is usually no individual that makes a specialty of all these activities of port organization for which millions of dollars are spent yearly and which so greatly affect the success of the undertaking.

The superintending engineer or marine superintendent of a steamship line, or whatever his title may be, usually has had years of experience in his field. In general it may be assumed that he has reduced the cost of ship operations at sea to a point where it would be difficult for any further savings to be made on a specific ship for such items as fuel, lubricating oil, and repairs. It would seem that the men who have made these excellent records for the operation of ship machinery would be naturally the ones to improve the methods of terminal operation. However, they do not usually have authority over the terminal work and perhaps consider it somewhat beneath their dignity. There has been too much of a tendency to consider terminal work a matter of driving men through a labor boss with a vocabulary amply profane. Perhaps the idealism of the engineering-trained man has made him retire from pier work to what Kipling would call his steam gadgets. Whatever the cause may be, at the present time, there are relatively few men in the terminal operations of shipping companies with mechanical training, not to mention engineering education.

Practically all the problems of a ship in port are of such complexity that a trained engineering mind is needed for adequate solution. Ships should be designed with a definite relation to the cargo. In so far as possible the ships and piers should be designed together. Naval architects have given the port needs of ship design much less attention than is deserved. Yet during the last few years quite remarkable improvements have been made in ship design tending to increase the speed or reduce the cost of a ship at sea. We now have electric drive, geared turbine drive, Diesel engines, pulverized coal, and many other methods for greater speed or economy on the ocean. Recent increases in speed and reduction in fuel consumption at sea have so reduced the costs incident to sea operation as to make costs incident to port operations "stick up like a sore thumb." There is a fascinating interrelation between all the factors entering into the cost of ship operation—change any one and it affects others.

During the time that these recent engineering improvements in ship design were taking place there has been a constantly increasing wage rate for stevedoring. One ship operator has said that it costs more to put the cargo into a ship and take it out at the other end than to move it from New York to San Francisco. Of the port activities stevedoring bulks so large that any increase in wage rates or decrease in effectiveness of labor

THE "TEC" (TECHNICAL ENGRG. CORP.) TRUCK RESULTED FROM TWO YEARS' ANALYSIS OF PROBLEMS AT EIGHT PIERS

(Prime features are large loading area, short turning radius, lift mechanism for separable bodies, ability to operate rapidly in either direction, crane attachment instantly available.)

seriously affects the owner of a ship. The work of handling ship cargo is not only severely arduous, but the accident rate is disgracefully high. Compared with usual industrial operation stevedoring work seems unnecessarily crude. The men themselves must realize this and may be justified either in leaving the field entirely or in asking still higher wages to cover the muscular strain and the danger hazard involved.

For the last few decades ocean carriers have been largely controlled under foreign flags. Our intercoastal business dates only since the opening of the Panama Canal and was much upset during the World War. American terminals have in many instances been managed by men in the employ of foreign steamship lines, temporarily assigned to authority in an American port. These men were thousands of miles from home and have had difficulty in getting authorization from abroad for making innovations or expenditures at American terminals. Under such circumstances should there be surprise that progress has been show?

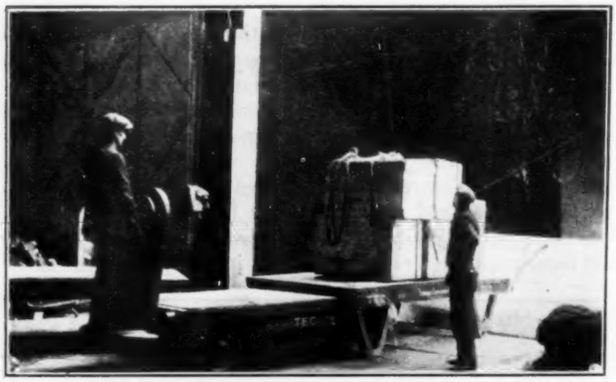
There is a more progressive spirit at Pacific Coast terminals than on the Atlantic Coast. However, the Pacific Coast piers are of recent construction, and the methods of operation have evolved according to the needs without being so heavily handicapped by precedent. But even on the Pacific Coast there is still almost unlimited opportunity for bettering terminal performance.

Americans may well be proud of their achievement in the han-

[1] President, Terminal Engineering Company, Inc., New York, N. Y. Mem. A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Materials Handling Division, Philadelphia, Pa., April 23 and 24, 1928.

dling of bulk cargo, ore, coal, grain, etc. But it is an easy matter to handle by machinery any type of uniform cargo whether in bulk or in packages. In the handling of package cargo there is little difference between operations in this country and abroad. The store-door delivery system, common abroad, is far in advance of our methods here for handling package freight at railroad terminals. Our railroad cars are so much larger than the cars abroad that shipments are accordingly larger here, and this makes the installation of machinery more feasible at steamship terminals where the wheels and keels meet.



By Placing Power Plant Below Level of Truck Floor There Is No Space Lost Except That Necessary for Driver

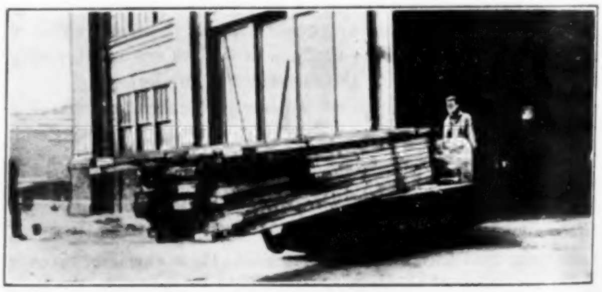
(The large size separable platform bodies permit handling more than one draft of cargo at a trip. The ideal is to have one steamship hatch worked by one truck.)

The problem of handling steamship package freight depends chiefly on the volume rather than on the weight of the goods involved. It is not at all difficult to build machinery to handle imported pig tin, lead, copper, etc. because the machines with ample weight load could easily maneuver in crowded quarters. To justify a power machine instead of the common hand truck it is necessary to have the power equipment carry enough volume of the bulky cargo to show an economical operation. The power-operated equipment on a pier has two major advantages over the hand truck in horizontal transportation; it can carry a heavier and more bulky load, and it can move it more rapidly. If in addition the power equipment can be supplemented with attachments that permit high stacking of heavy freight, there is great advantage on the side of the machine as compared with the hand truck.

The operation of loading a ship is more simple than discharging because sorting is usually involved in the discharging operation. A comparison of the hand-truck loading and machine loading of ships will be sufficient to indicate some of the fundamentals of the problem. It is customary to make up drafts of freight, each weighing approximately one ton. When hand trucks are used several hand-truck loads are necessary in each draft for the ship's tackle. Making up of a draft at the side of a ship causes congestion in a space only 10 ft. square. The effectiveness of the work in this small space largely determines the length of time the ship must remain in port. Also the bringing of various hand-truck loads to the side of the ship to make up a single sling load usually results in a mixing of the freight and breakage to the cargo, since the sling might include more than one type or size of package.

It is essential to bring drafts to a ship completely made up ready for hoisting and to take them away from the ship complete rather than in numerous hand-truck subdivisions. A complete draft of a ton or more is too heavy a unit to be moved horizontally by hand labor. If the management asks the average pier foreman to apply machinery and improve his methods, he is likely to begin by considering a tractor to pull the four-wheel hand trucks. The tractor sounds cheap and is often expected to work a revolution without any replanning of related equipment and conditions. Should a power tractor be used to pull completed drafts the combined length of the tractor equipment and the freight becomes serious. Also tractor equipment is not capable of backing out satisfactorily from blind alleys. Another point seldom thought of is that the ordinary four-wheel hand truck is not at all satisfactory as a trailer. Good trailers for pier use are expensive, and the combined investment of any tractor with sufficiently good trailers becomes much more than usually contemplated. In crowded quarters tractor operation is slower than lift-truck operation, and there is much more shaking off and damage to freight because of the vibration if trailers are not equipped with leaf springs and good rubber tires. If trailers are equipped with springs and rubber tires, the investment and the maintenance become large because of the great number of trailers necessary.

In 1912 and 1913, during some advisory work for the Bush Terminal in Brooklyn, the author had an assistant observe every type of freight handled on the seven large Bush piers each morning for a whole year. By this method there was a study of all the different classes of freight handled seasonally. It is believed that these studies are the most complete ever made of the problem of handling export and import pier freight. Tractors and trailers were thoroughly studied in service and proved deficient on the grounds stated. The following features were found essential for any type of equipment to handle the numerous classes of freight found on steamship piers:



Though Not Designed Primarily for Lumber, a Standard "Tec" Truck Can Handle 16-Ft. Lumber From Shipside to Pile

(Lumber is now so frequently a partial cargo that it is desirable to have one type of pier equipment handle both lumber and general cargo.)

1 Area sufficient for more than one draft of usual cargo
2 Smallest possible space occupied for a given volume of freight
3 Lift mechanism for use with separable platform bodies
4 Shortest possible turning radius
5 Quick acceleration
6 High speed with safety
7 Ability to operate equally well in either direction
8 Ample rubber tires and leaf springs throughout to give least shaking effect on rough floors
9 Legs of separable platform bodies to be opposite truck wheels
10 Ability to negotiate 20 per cent grades with loads to or from lighters or side-port ships
11 Tractive power sufficient to shift freight cars
12 Design arranged for pushing freight by sliding on pier floor
13 Automatic coupler so that lift truck can be used as tractor whenever trailers are of any advantage

14 Small fire risk for use through side-port ships
15 Ability to handle material 20 ft. or more long
16 Quickly attached power-operated accessories
17 Instantaneous crane attachment for lifting drafts made up directly on the floor
18 Low center of gravity to permit high stacking with crane attachment
19 Unit construction necessitating smallest possible number of different repair parts
20 Lubrication arranged for minimum attention
21 Ability to operate through city streets and over railroad tracks adjacent to terminals
22 Versatility sufficient to handle effectively any style of cargo worked on a pier.

Electric storage-battery trucks built on the foregoing lines have now had years of service on steamship piers handling practically every kind of freight that comes to a pier. A check of the principles has shown their correctness, and vast savings to shipping are possible by further application along proved lines.

The use of the crane attachment for a truck with an alternative set of lift bodies permits the working method to be changed if necessary every few minutes throughout the working day. Where the freight is light and bulky the lift bodies may take on one trip what might require several trips with the crane. If the material is too heavy to lift on the separable bodies—for instance, oil or chemicals in barrels—several barrels can be carried at one time with the crane attachment. If high stacking is necessary the crane attachment can save much human labor. Although numerous types of attachments can be applied to this type of electric truck, the handling of miscellaneous cargo requires that any kind of package be worked without too many different kinds of attachments and only one size of truck.

The technique of freight handling on steamship piers has been built up over a century or so of using the hand truck. The ordinary point of view is to use the hand trucks most of the time and mechanical equipment only on special jobs. This code is being reversed, and there are now some steamship piers on which a hand truck is seldom seen. The thing to do is to apply the

When Warehouses Are Located Close to Terminals It Becomes Feasible to Have Freight Move Directly From Steamship Pier to Warehouse

(The saving in rehandling and in pier congestion may pay handsome dividends.)

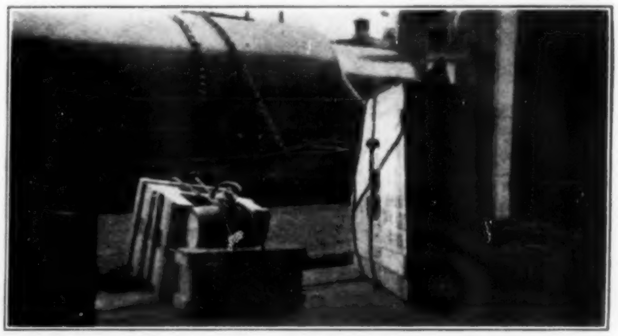
machinery and develop the right method for machine trucking for each particular class of freight just as hand-truck methods have heretofore been developed. The pier workers themselves are interested to make the work as easy as possible and in the aggregate will furnish many of the ideas for the ultimate best machine methods.

Ships have increased greatly in size during the last 15 years. Most ships tie up at piers built in an age of smaller ships and cargoes. As a result there is not enough space on the pier itself to hold the cargo. Either the ship must be moved, if the pier has sufficient length, or the cargo must be carried long distances lengthwise, piled high in the air, or some combination of these methods used. This factor of big cargoes has greatly increased the length of trucking distances and the height of piling. Distance does not make a material difference to mechanical methods, but it vastly increases costs if hand-truck methods are used. High piling is still done largely by hand because sufficient study has not been given to the application of machine methods.

Sorting of discharged cargo costs hundreds of millions of dollars yearly, and practically nothing is being done to remove the cause.

A Crane Attachment Which Automatically Locks to the Truck Is Picked Up Whenever Needed

(By applying different methods or attachments the Tec truck can be quickly adapted to any type of cargo.)



When Loading a Steamship, Drafts Should Be Brought to Shipside Already Made Up

(By bringing the drafts to shipside already made up several drafts can be accumulated ahead of the ship's winches.)

Fundamentally, sorting is due to the small size of the packages of freight. Packages have been made man size rather than machine size. The chief difficulty in sorting lies in the lack of cooperation between the loading and unloading organizations at the two ends of the ship's run. Ships are often scheduled to stop at many ports, and the sorting involved at the point of discharge is a composite of the loading methods at all points of origin.

Unless some one man or group of men is constantly studying this situation, unnecessary costs owing to sorting of cargo are sure to result. Of course not all cargo can be stowed simply, as it is frequently necessary to pack the smaller packages between the larger cases of machinery. Because of the diversity of the American manufactured products there are all kinds of sizes and shapes exported. Typewriters must be loaded with locomotives. Discharging a cargo of diversified manufactured products is justifiably more complicated than the handling of the

raw materials imported into this country and discharged at American ports. We should be able to improve greatly on the methods of discharging in this country since much of the inbound freight comes in large lots of one size or kind of package.

Where the packages are all of one size or shape it is the sorting according to the identification mark on the packages that causes tremendous confusion, delay, and expense. If the packages are not stowed in the ship so that packages of one mark can be easily segregated, then the drafts from that ship may seem to contain even more marks than there are packages. Labor is cheaper in all other parts of the world than it is in this country. Every steamship operator should wage an increasing campaign to see that cargo is so loaded at foreign ports that it can be most cheaply and quickly discharged here. One prominent freight line has recently reduced its American direct costs of discharge approximately 20 per cent on an average of six months as compared with the preceding six months. This was done chiefly by proper stowage on the ship by which freight was put into blocks according to the marks. With the block stowage it is possible to make up drafts inside of the ship so that they may be hoisted out one mark to the draft. By using larger drafts and machinery on

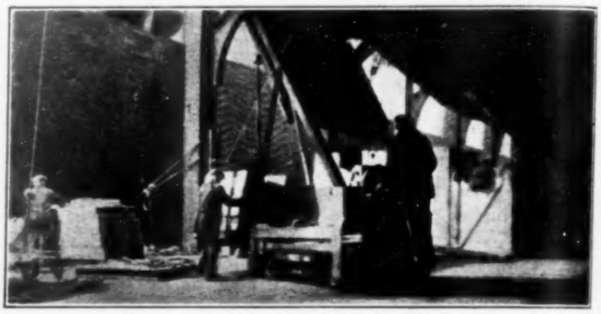
Block Stowage of Cargo Inside Ship Permits Taking Directly to the Pile Full Drafts of One Mark

(A special sling arrangement allows the use of larger drafts and the sling can be so picked up by the crane as to avoid slack of the sling rope and permit machine piling as close as possible to ceiling of the pier.)

the pier it is a simple matter to get the freight directly to the proper pile on the pier as the whole draft can then go to just one pile. Freight is high in the air when it comes over the side of a ship. The higher it is carried by power trucks across the pier the smaller the amount of labor required to stack on the pier.

With proper study there would seem to be no excuse for the continuation of hand-labor methods for sorting bags of coffee, bags of cocoa beans, castor-oil beans, etc. Practically all the coffee arriving in New York is "humped" by men carrying 130-lb. bags on their shoulders. Coffee is so mixed in the ships that a postoffice operation is required to sort each bag to its place on the pier.

Even though cocoa is loaded on the African coasts in surf boats where men wade out through the water to these boats with one bag at a time, there are possibilities for getting the freight into the ship so that it would not be necessary for men to carry each bag in America where the longshoremen get 85 cents an hour with time and a half for overtime. As many as 70,000 bags of castor-oil beans have recently arrived in New York on a single ship



Trucks With Crane Attachment Carrying Full Drafts on Aeroplane Slings

(Cranes supported on the pier structure cannot work outside the pier shed or cross over easily from one aisle to another.)

hopelessly mixed in the stowage. It is not easy to engage men who are able to carry these heavy bags of 160 lb. each. Certainly the men themselves would respect their employers more if the employers made the work simpler and easier.

A rope sling is commonly used in handling bag cargo. The rope sling remains today in the same form as it was when man first put freight into ships or developed rope manufacture. If a draft of bags or other materials is taken from a ship in a rope sling, the draft tends to fall apart the moment it reaches any support to carry the weight. For a century or more pier workers all over the world have attempted to catch the draft at the moment of its landing and so hold the sling rope as to keep the draft together. Some such method is necessary if drafts as a whole are moved away from the ship direct to a pile. There has been great loss of time and breakage of freight due to the drafts falling apart while being moved on the pier. This is particularly true when drafts are placed on trailers without springs or rubber tires and moved at high speeds. Then, too, the falling apart of the draft often causes smaller drafts to be used in an attempt to remedy the condition.

There recently has been developed a device known as a sling "tek" which can be placed on any rope sling to make it automatic. The sling tek slips to the tightest position and holds the sling at that point. When desired the locking cam is quicky released by hand or foot pressure. Larger drafts are possible and drafts can be landed more quickly, since there is no possibility of their falling apart.

Another economy feasible by this device results from the ability to carry all drafts of any kind by crane equipment by merely hooking the crane directly to the tek, thereby eliminating the headroom usually required by the long end of the sling. This point is important because it permits the use of pier machinery to pile the drafts where with the long sling there would not be sufficient headroom to make mechanical piling effective.

In many parts of the world ships must still be loaded from lighters. It is difficult to make up the drafts with the lighter

pitching in rough water, and the ship itself is likely to be delayed. A simple hoist on the shore might lift whole drafts to or from lighters. Wherever lighters are used there is a possibility of equipping each lighter with a quota of non-slipping slings to obviate the rehandling of separate packages at each end of the lighter movement.

Some one who has the proper inspiration could make a fascinating study as to how the many commodities in foreign commerce happened to become standardized in the various odd sizes, shapes, and weights of packages for each article. But more important would be a study by the United States Department of Commerce as to the possibility of recommending changes in the packages. Consider plantation rubber from the East Indies. This huge commerce has developed within the last few years. The material is so valuable that each package is checked and rechecked. There might be as many as 100 separate clerical

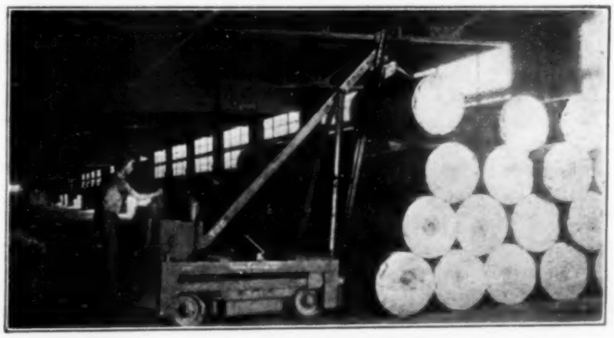
LARGE SHIPS FREQUENTLY CARRY CARGOES TOO BIG FOR PIER AREAS AVAILABLE

(The use of mechanical equipment at terminals facilitates handling freight over large adjacent areas. In the illustration above Spanish olives were sorted over acres of sand fill adjoining the pier. Carrying the 1500-lb. casks instead of rolling them eliminates the opening of seams and lessens the spoilage due to leaks in the casks.)

transactions in the history of any case of rubber from the time it obtains its identity to the time its existence ends in a rubber mill. Why did it happen to be a nearly cubical package with six faces, any one of which might contain the elusive identification mark? The weight, around 220 lb., is heavy for Malay physique and is too light for effective machine operation. If rubber were packed in packages of 1000 lb. or even 2000 lb., sorting would be simplified, since power equipment could readily take each package to its proper pile and quickly stack it as high as desired. Larger packages would automatically reduce not only the danger of theft, but in the ratio in which the packages are made larger, reduce clerical work, weighing, sampling, etc.

How did it happen that in this same East Indian territory burlap has long been shipped in large bales weighing from 1000 to 1500 lb.? A package of this kind is large enough to be economically handled by machinery carrying one package at a time directly from shipside and tiering on the pier 12 ft. high with negligible costs for the tiering. Burlap was formerly one of the difficult kinds of freight to handle because the longshoremen complained of the weight of the packages. They could not tier the bales high because it was impossible to get enough men around any bale to elevate it. Today with machinery burlap bales are ideal freight to handle, and the handling cost per ton is lower than for almost any other commodity. Another good type of package for mechanical handling on piers is newsprint paper in 6 ft. rolls weighing about 1300 lb. each. By special attachments on electric trucks this paper has been handled from shipside at the rate of from 40 to 50 rolls per hour per truck, sorted and stacked four rolls high on the flat, without a human hand touching the paper after landing on the pier.

Customs weighing of imported cargo by the Government employees has long been by antiquated methods with great expense



CARRYING AND STACKING 1300-LB. ROLLS OF NEWSPRINT PAPER

(An attachment for the Tec crane permits each truck operator to transport and stack 40 to 50 rolls per hour. No helper is needed.)

AUTOMATIC BURLAP-CARRYING ATTACHMENT FOR TEC CRANES

(This burlap attachment can be put on in a few minutes. It automatically grabs a bale of burlap and allows horizontal and vertical movement for stacking three bales high. One operator can handle 60 to 70 1500-lb-bales per hour.)

and delay. If mechanical equipment is used there are many possibilities for moving the freight over scales in the course of the regular operations, thus eliminating rehandling and consequent delay to valuable freight. It is only within the last year

that sugar going into public warehouses in the port of New York has been weighed in 3-ton lots by running electric trucks over the scales. The amount of sugar stored in New York alone may be 200,000 tons in a season. The engineering side of weighing is not difficult. It is chiefly a matter of organization to apply the engineering principles.

Better design of ships from a cargo standpoint may result in making many ships almost obsolete within the next few years. The problem has been so little studied that it is impossible to foretell the nature of the changes. Whatever they may be

Burlap Bales Stacked Three High on End

(It would be impossible to stack these heavy bales this high without the use of mechanical equipment. Not only is the time of the ship saved by moving the bales more rapidly but the capacity of the pier is doubled.)

however, it is pretty safe to predict that they will be revolutionary.

The new *California* of the Panama Pacific line, the biggest merchant ship built in American yards, has numerous side ports large enough to take a sedan car. Electric trucks can be run through these side ports without any objection from the underwriters who might not allow gasoline equipment. A side-port ship having large hatches might be equipped with elevators so that electric trucks can take the package freight directly to the proper part of any deck of the ship for stowage. This obviates the necessity for placing freight in slings just to get from one deck level to another. It might be desirable to have an elevator cover only half of the hatch area and use a hoist mechanism for the other half, so that the elevator hatchway itself may be filled with freight after all other portions of the ship are stowed.

Much bulk grain is loaded while ships are at general-cargo piers. Trimming the grain has been an expensive and time-consuming operation. Mechanical equipment for trimming grain in ships is now available and should be more generally used. Again it is a matter of organization, because of the divided responsibility between the grain elevator crews, the shipowner, and the contracting stevedores. Grain is often handled in tramp steamers, and the ship's agents seldom understand the possibilities of mechanical trimming.

Ships in foreign trade are on such long runs that they cannot be operated on any schedule which will keep the terminals continuously busy. Ships will bunch at the terminals no matter how carefully they are timed, and there are sure to be days or even whole weeks without any ships whatever at a given pier. Even the largest shipping companies would hesitate to purchase enough mechanical equipment to load or discharge all their ships that might be in port simultaneously. They could perhaps provide for their minimum or even their average requirements, but not the maximum. Then, too, it is not only a question of investment in equipment but of having enough highly skilled operators available when necessary. The effective operation of marine freight-handling equipment requires men of a quite unusual type. Unless these men are given sufficient continuous work they will drift away to other industries.

Commercial stevedores are paid on a tonnage basis, and it would be supposed that they would have the incentive to develop or buy the best machines for handling marine freight. Stevedores have, however, been at a disadvantage in that they have usually had too little certainty of continuing the business with any single ship owner. It has been too big a risk for them to invest in sufficient mechanical equipment to do work on an all-machinery basis.

The best thing that can happen to a ship owner's bank account is the elimination of the hand truck from his piers. There seems to be no likelihood of sufficient mechanical equipment at steamship terminals to banish the hand truck except by a rental service. Versatile mechanical equipment must be mobilized in sufficient quantity at any pier as needed. This requires rented freight-handling machinery with professional skilled operators.

Much of the miscellaneous gear used by steamship lines or by contracting stevedores is unfortunately not of the best design for the purpose, and therein lies opportunity for men with engineering training. The average longshoreman cannot be expected to select the one best method for the various kinds of freight which change every few minutes during a working hour. When power trucks instead of hand trucks are used on a pier the truck operators can be of tremendous value by using their greater mechanical experience to guide all the other men in the gang. When the hand truck is eliminated, old habits of work disappear and there is a zest in the job which creates new performance records

Pacific Coast Timbers Are Too Large and Heavy for Man-Power Handling

(By use of mechanical equipment these timbers can be easily moved rapidly.)

without conscious effort on the part of the men most intimately involved.

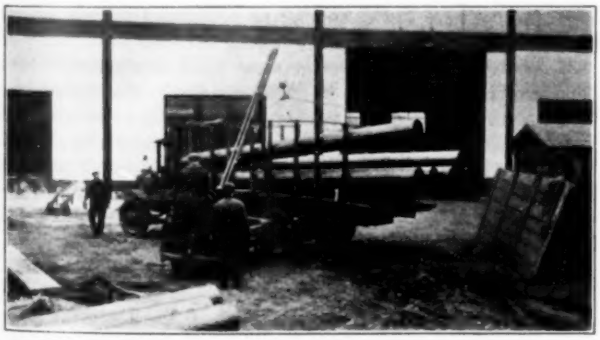
Mechanical freight-handling equipment should move at speeds three to five times that of hand trucks. Usually first installations of machinery on steamship piers use the power equipment on only one or two hatches of the ship. If the other hatches are worked by hand trucks, power equipment can travel no faster than the hand truckers using the same aisles. Mixing the methods is unnecessarily dangerous for the hand-truck pushers and it does not give a fair comparison with the machine methods. Until all pier operations are done by machinery without any hand trucks to get in the way and slow up operations, full economies will not be realized.

Overtime wages at 50 per cent increase are watched most carefully in the offices of ship operators. Not only does the cost per

ton go up because of the overtime wage rate, but there is a decrease in the tonnage because the men become tired from long hours of work. Machinery does not get tired and can work at high efficiency all night. There is an advantage in working many of the busy terminals at night because at night there is freedom from the congestion of motor trucks, taxicabs, etc. Few ship owners realize that power trucks on the pier need cost no more for night operation than for day operation. Although the truck operator may get an extra 50 per cent wage rate at night, the reduction of overhead charges on mechanical equipment offsets the overtime wages. So far as the pier operations are concerned, a look into the future seems to indicate regularly working all around the clock. Ships are getting so much larger and more expensive that quicker turn-arounds are sure to be demanded. A ship is active all of the 24 hours when it is at sea; why should it waste so much time in port?

Until recently operations on steamship piers rather than inside the ship have determined the speed of loading or discharging cargo. This has been owing chiefly to the assembling and disassembling of cargo drafts immediately at the side of the ship. Where mechanical equipment is used to bring full drafts to the side of the ship and take them away from the shipside, the whole pier operation is changed. Mechanical equipment on the pier throws the weak spot of cargo handling to the inside of the ship itself. Stowage of miscellaneous cargo is at best highly complicated, and every possible attention should now be given to this phase of the work. The naval architect will be needed to assist in transforming ships so that the cargo inside the ship can be handled with more dispatch and less muscle.

Ship terminals have mostly been designed by the civil engineer whose chief thought has been the under-water construction. The upper portion of the pier, which affects all of the cargo handling, has received relatively little attention. All concrete and steel design for the freight section of any pier should be planned around the mechanical-engineering features. It is practically impossible properly to fit the mechanical engineering into the

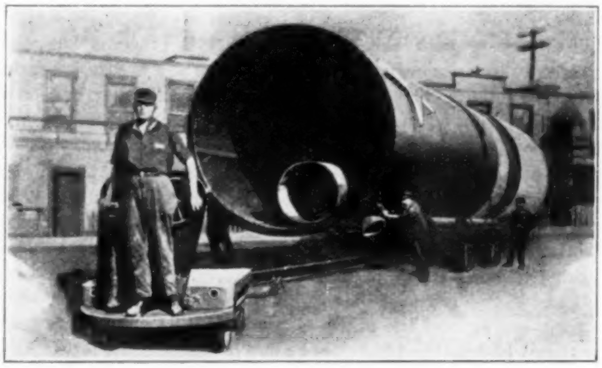


TERMINAL CONGESTION CAN BE RELIEVED IF IMPORTED FREIGHT IS TAKEN AWAY FROM THE PIERS PROMPTLY

(There is also a reduction in the accident rate if heavy articles are lifted by machine methods.)

civil engineering after the terminal is completed. Take for example the matter of elevators for two-story piers. These elevators are seldom large enough and they are often so spaced as to cause unnecessary congestion in freight handling. In ports where lighters are used, piers should be equipped with ramps to permit running electric trucks on and off lighters; proper location of such ramps requires in itself very nice study. Many piers are built with outside aprons so narrow that throughout the whole lifetime of that pier there will be unnecessary labor and delay for freight handling and excessive damage to cargo.

The use of mechanical equipment at steamship terminals permits taking the freight any reasonable distance without increase in cost. There is nothing to prevent piers being made 600 ft. or more wide. Also power equipment permits carrying freight immediately away from shipside for storage in any nearby area. In New York City 5000-ton cargoes of Holland or Belgian brick are regularly transported and piled in spaces perhaps one-quarter of a mile from the pier berth. Also cargoes of Spanish olives in barrels or hogsheads are regularly sorted over several acres of sand fill adjoining the pier. From an engineering standpoint



SHIP OPERATION FREQUENTLY REQUIRES THE HANDLING OF LARGE, HEAVY MACHINERY.—INDEPENDENT FOUR-WHEEL DRIVE OF THE TEC TRUCK GIVES GREAT TRACTION FOR PULLING OR PUSHING HEAVY PIECES

(The varied types of work shown in the preceding illustrations are chiefly of interest in that they have been handled economically by one model of Tec truck with a few attachments which can be instantly applied.)

it is perfectly feasible to take large lots of cargo directly from the ship to any floor of nearby city warehouses. Thus if ships have large side ports and elevators, Pacific Coast canned goods can regularly be moved directly from any portion of any ship deck to any part of a nearby wholesale warehouse.

The same ships and the same men in the crew are involved in each end of a ship's run. This is entirely different from railroad operation. It should not be so difficult to get freight put into a ship at one end so as to get it out of the ship properly at the other end. Coolie labor is low in cost, but expensive for supervision. Use of mechanical equipment in tropical ports is often justified on the ground that less mixing of cargo gives a large saving at the American ports.

Longshoremen in this country cannot be expected to do the heavy cargo handling work that they did in former years. As the saying on the Atlantic Coast goes, "In the old days we had wooden ships and iron men, now we have iron ships and wooden men." It is up to the ship owners to change the working conditions. A contracting stevedore cannot do it alone, because he has no control over the loading of cargoes in ports other than the one in which he is the contractor.

The high accident rate and great insurance expense should be sufficient to get the ship owner's attention. It has been proved on the Pacific Coast that most marine accidents can be eliminated by competent engineering study. Accident-prevention work alone is sufficient justification for more engineering-minded men at ship terminals. The use of more machinery and less hand labor is definitely known to reduce accidents. Reduction of accidents automatically gives better economic cost.

Men properly qualified to make improvements in ship-terminal operation do not exist in any great number. The question of getting results is therefore a very real one. Perhaps the easiest way to make a beginning would be to have carefully picked men put in training for this work and serve first on a purely staff basis, reporting directly to the general manager. In this way

there would be no upsetting of the authority of the pier organization responsible for turning the ship around in the least time and at the lowest cost. These special men should be given every possible encouragement from the top officials of the organization. They will need it, and unless they get it they may leave the shipping field and set back the whole effort to an entirely new beginning. Unfortunately there are too few general managers who themselves understand the terminal problem sufficiently well to advise and back up these selected men during the period necessary for them to become familiar with all phases of the work.

Connection with the general manager's office is suggested primarily because only at the top are there any cost or statistical figures available to stimulate imagination and spur one on to making further studies. No two cargoes are alike and the business may change entirely at different seasons of the year. A rough and ready ability to think in terms of statistics is desirable. A beginner should be warned, however, against trying to prove too much by cost figures or even the simplest motion studies. The operations are usually so crude that the problem becomes primarily one of judgment and ingenuity. A valuable process for quick test purposes lies in comparing two methods by balancing one against the other, factor by factor, and quickly ascertaining which method has one or more predominating advantages. After some experimenting the investigator will gain confidence in his own judgment and know almost instinctively when a freight-handling operation is moving properly without using a stop watch or other timing methods.

Marine-terminal work is more than usually interesting, and there should be no difficulty in getting the right type of men to enter the field if they are assured proper cooperation and support. There is a need for more men who speak the language, which need not necessarily be profane.

## Discussion

H. E. Stocker.[2] I think that the author is working along the right lines, but disagree with him on lift trucks as compared with tractors and trailers. The thing that interests me is that a tractor can haul a train of trailers for long distances on a pier, 1500 ft. long for instance.

An important point is the coordination of mechanical equipment, whatever it may be, with the remainder of the operation. There is some inclination on the part of terminal-operating steamship men to buy, say, four or five lift trucks and the necessary number of skids and shove that equipment into the operation without a comprehensive study of the operation so as to get the maximum advantage from the new equipment.

As the author says, shipping has not kept pace with manufacturing. Shipping management has not developed as rapidly and as comprehensively as manufacturing management.

In shipping we need more of an engineering viewpoint, and with that there is bound to come a greater development of mechanical handling. Executives for the most part are not trained in the management principles that have done so much for manufacturing. If that is done it will undoubtedly bring a revolution in shipping and make it possible for American ships to reduce to a large extent the handicaps encountered in competition with foreign shipping.

Recently in Chicago I saw the operation of the Goodrich Transportation Company, and the same day I saw the operation of a manufacturing concern where they keep the material on wheels or the equivalent. The Goodrich Transportation Company applies that same principle. They receive the freight on trailers for the most part, keep it on trailers until it is pulled into the ship through side ports, and leave it on trailers while being transported to its destination point.

The principle of standardization can be applied in shipping to a very large degree. I have been on piers where they used two or three kinds of equipment to handle exactly the same class of cargo. One of those is the best, or there is some other class of equipment on some other pier that is the best and that certainly should be used in every instance.

The author is on the right track. We need more men in shipping who will approach the cargo-handling problem from the engineering viewpoint. It will be a substantial step forward if shipping men can be induced to join societies such as The American Society of Mechanical Engineers as associate members. It will be a step forward also if the Society will take a greater interest in shipping problems. Papers of this nature do much for shipping and widen the field for mechanical engineers and for manufacturers of mechanical equipment.

R. L. Lockwood.[3] To a certain extent these questions of standardization that the author has brought up have been put up to us, but so far the work done has been confined almost exclusively to domestic shipping problems and to domestic containers, and there has been very little done with export containers and nothing at all with import containers, except imports from foreign branches of American companies. There is a little work going forward on that.

Recently the question of standardization of lift trucks and skid platforms to secure interchangeability at both ends of the line has been brought up to us forcibly by many shippers, by at least three railroad companies, and by a number of manufacturers. It is too early yet to make any statement about what will be done.

We realize that the matter of shipping on skid platforms, either "live" skids or "dead" skids, is interesting manufacturers of many different commodities. Some motor-car companies are demanding that certain goods be delivered to them on skid platforms. There are a number of companies owning several plants that make a practice of shipping between those plants on skid platforms. They have the same truck equipment at both ends and can easily handle it. The savings by that method are said to have been large. One instance was in paper shipment and another one of pulp. The saving in material alone with a temporary nailed skid platform has run as high as 77 per cent as compared with the cost of shipping in packing cases. Loading on a skid platform and loading the platforms into a railroad car instead of packing the goods in cases and loading them in a railroad car has shown as much as 90 per cent saving in labor. One railroad system is using skid platforms and lift trucks for handling railway stores between different stores points on its own lines. Figures indicated that in one year they cut down the number of cars in that service almost one-third, and made a cut in labor cost of about 65 per cent. J. V. Miller, who is assistant general storekeeper of the St. Paul Railroad, has been particularly active in that work. In a recent article he made a statement that I think sums up the materials-handling situation from the viewpoint expressed by Mr. Hagemann; that handling materials, as distinct from transporting them, adds to cost, but adds nothing at all to value. Any gain made in cutting down the cost of mere handling of materials as distinct from transportation is a net gain.

The Division of Simplified Practice is now gathering information from railroad companies, shippers, and manufacturers of equipment, and within a few months, judging by the progress

[2] Munson Steamship Line, New York, and McCormick Steamship Co., San Francisco.

[3] Division of Simplified Practice, Department of Commerce, Washington, D. C.

in the last two or three months, we shall have a mass of material available.

It has been suggested that we make a number of studies of the possibilities for standardization of skid platforms, with the idea of determining certain national standards of dimension, particularly the clearance height under the platform, so that all kinds of lift trucks can handle the same platform; the width between runners or legs of the platform; and the overall length and width, so that such platforms can be loaded economically into a railroad car. The St. Paul people developed a size of platform that can be loaded lengthwise in a 50-ft. boxcar, three platforms wide and four rows deep to the door, making 12 platforms, and then 12 on the other end. By this arrangement they can get a larger proportion of capacity carloads, whereas formerly the average carload in that service was very much below capacity.

The necessity for fitting standard skid platforms to a railroad car is of course of first importance. There are therefore three points to be considered. Apparently the clearance height of the platform affects more different kinds of equipment than anything else. Perhaps the width of the platform between runners is next in importance, and then comes the overall length and width to fit into a railroad car. That is as far as we have gone. We all realize that this problem extends into almost every field of manufacturing and shipping, other than the handling of bulk cargoes. There are thousands of commodities that are handled now and that have been handled for years in and around plants on skid platforms. Very few have been handled between plants or on railroad shipping platforms. That practice is growing very fast. In order to avoid chaos as it continues to grow, it will be necessary soon to have interchangeability of equipment. The same conditions are developing in this as developed years ago in the railroad business, when interline use and car exchanges began, and the necessity for interchangeable couplers, standard gage, and other standard features of railroad equipment became evident. Today such standards are accepted almost as a law of nature, but they are actually results of cooperation. The same sort of cooperation between shippers, railroads, and manufacturers of equipment must be secured before such results can be accomplished in connection with lift trucks, skid platforms, and similar equipment.

The Department of Commerce will cooperate in every possible way to that end. It has been represented to us that the direct cost of shipping materials which can be handled on skid platforms from shipper to consignee runs from seven hundred to eight hundred million dollars per year in this country. Savings made by shipping on platforms in certain instances have run as high as 90 per cent in labor and 70 per cent in material. Estimates run from a possible saving of 10 per cent to 50 per cent on the enormous figure mentioned, but as yet we have been unable to verify the figures. It is all up to the industries directly concerned, and the matter is being seriously considered. We are going to do everything we can to help it.

C. B. Crockett.[4] Would the author care to discuss the inherent possibilities of the dead skid and the live skid, and the question of taking material from steamships, particularly sideport operation, by the use of the lift truck, where it is possible in most cases to get a skid load for one consignee but the very next skid load may be for a different consignee, and the ultimate placing of that widely separated material. Is it possible to work out a method by which lift trucks can take the material from the ship on live skids and so classify them that they may be taken down to pier by the tractor trailer method and dropped off at the proper destination? The question in a great many cases, as I understand it, is that the use of live skids is dependent upon the rapidity of movement of the material and how long it has to be stored.

One of the New York Central engineers recently said that they would like to use live skids, but that the investment was too high because they had to keep the material on the pier sometimes for as long as 28 days. They are therefore using the dead-skid method. The author has had experience with the use of the two methods and might explain the limitations of both the dead and the live skid.

[4] Society for Electric Development, New York, N. Y.

### Author's Closure

Mr. Andjeski, of the Cleveland Terminal Railway, inquired about the capacity of that truck and the speed with which it operates. It is of 3 tons' capacity and runs 10 miles an hour empty and about 8 miles an hour loaded. The speed can be made higher or lower if desired.

I shall answer the questions of Mr. Crockett and Mr. Stocker together. Mr. Stocker asked regarding lift trucks and trailers. I hesitate for fear some of my friends in the tractor-trailer industry may misinterpret my remarks. Trailers in this class of service on piers ordinarily are not larger than 3 x 6 ft. That size will not take more than one draft of ship cargo. The principle I have been working on has been to put freight on a lift platform. I call it a separable body, for it is not a skid, and the word "skid" is a misnomer. The word "skid" originally meant something like a machinery skid that had continuous members instead of legs as a support for the platform. We have mostly outgrown the skid type of lengthwise member, and we have placed legs on the corner of the platform. I believe the word "skid" is unfortunate and should be dropped.

Now if a load were put on a lift platform, or separable body, as I call it, the speed of movement can be increased because of traveling on rubber tires and springs. I want to bring out that point in different ways because otherwise I might not make myself clear. Taking steamship operations and terminal operations, there are seldom more than two or three trailers used behind one tractor. It is possible to put a dozen trailers behind one tractor but they are not seen that way in actual practice. Many times one will see just one trailer running behind a tractor. I doubt if the average exceeds two. Now suppose we put upon a lift platform as much freight as can be placed on two or three trailers. It can be run at higher speeds. It can back out of a blind alley. The goods will not shake off. The platform is cheaper for a given volume or weight of freight than the combined two or three trailers to take the same goods. That is indicated in the methods of the New York Central Railroad where they want to hold the goods temporarily. I consider these lift-truck bodies as sections of a floor of a warehouse or pier. Let the goods remain on the platforms as long as they possibly can. It then comes down to the quite simple problem of the cost per square foot of these platforms, sections of a floor they might be called, so as to permit as far as possible the leaving of goods on the platforms until they must go through the next process.

In Seattle recently a prominent shipping man was mentioning the handling of raw silk from China. It must be inspected by the customs officials between the time it comes off the ship and goes into an express car. Special trains are run across the continent to New York for this silk. He asked, "Why lay it on the floor for customs inspection when you are moving it on special trains across the continent? Let it remain on the platforms until inspection is completed." I think there is no question but the next step is going to be the using of platforms in quantities so as to save a handling or two of the goods. If merchandise can be left on the platforms for customs inspection and weighing, taking care in sorting to have one lot on one platform, as far as possible, the deciding factor then is the cost per square foot.

The speed of the tractor and trailer on piers is usually slower than that at which lift trucks are being run. The speed of a tractor and trailer is comparable, perhaps, with the speed of the usual indoor lift trucks. The lift truck shown in the paper has 50 to 100 per cent more speed than any lift truck of which I know. That speed can be used if there is ample power and a spring suspension and if there is enough rubber in the tires. There is twice as much height of active rubber in these tires as is in the standard tires on what we might call indoor lift trucks. The old S. A. E. industrial-truck-tire standard was for 2 in. high including the metal base. The metal base was about $^1/_2$ in., the hard vulcanized rubber about $^1/_2$ in., leaving 1 in. of live active rubber. I accepted the outdoor S. A. E. tire standard of 3 in. total height. The metal base and the hard rubber are the same, but there is 2 in. of active live rubber. This gives a possibility of higher speeds over rough floors or rough ground.

The tire heights for street trucks are somewhat different now because higher tires are being made, so that the tire standards are all mixed up so far as street trucks are concerned. I am making the comparison as giving some possibilities for running at high speeds. Tractors and trailers ordinarily run at a lower speed on a steamship pier than do lift trucks because goods must not be shaken off. Also with the trailers, even those of the best design, there is difficulty in steering at higher speeds so as to not hit any piles of freight on the pier.

As to the question of live and dead skids: putting anything in the nature of castors on skids very greatly increases the first cost. I have designed some castors, better than anything I could buy, to get more ruggedness and better bearings, so as to make it possible to push a 3-ton load on the lift platforms illustrated. The conclusion I have reached in my own studies is to handle everything possible by machinery. With castors there is an implication that the skids are going to be pushed by hand. I say, do not push by hand; move by machinery. That involves sorting on the discharging end, if possible, inside the ship. Load merchandise so that when discharging it is not necessary to sort it outside the ship; do it inside. The stevedores may say that this cannot be done. I can show great savings by companies that are doing it. The stevedore who has to discharge ships usually does not control the loading at the other end. When he loads an outgoing ship at his pier he says, "Let the other fellow worry. My job is to get that ship out on time. The other fellow has to discharge the freight. I have loaded it so that it will not shift inside the ship. That is my job, to stow it safely and get the ship out on time." That is typical all over the world. If we get the goods out of the ship the right way, we should not put castors on skids or platforms, but we should use machinery. I try to put it to my men in this way; "If we were going to heaven, and going to handle freight in heaven, how would we revamp our methods?" And we reckon the ultimate in heaven and seen how close we can come to it on earth. I believe the use of castors on a steamship pier is a step in the wrong direction by which we are likely to set precedents that we shall want to change later. If castors are used, people will expect to push by man power for the next ten years. Don't do it. Let's move freight by machinery, and if we can't move it by machinery under present conditions, let's change the conditions.

John A. Grove, of the Atlantic Refining Company, has asked if there is any satisfactory means, other than by the winches and slings, of handling mechanically a uniform package to the interior of vessels without side ports, such as by a booster conveyor or spiral conveyor taking the package to the stowing point. That is a very interesting question. Side ports on steamers are worthy of a discussion by this Society. On the Pacific Coast last fall I found that the *H. F. Alexander* was built with side ports with the expectation of running coastwise on the Pacific Coast. Perhaps the insurance underwriters took literally the word "pacific" and thought it was all right to have side ports of large size on the Pacific Ocean. During the war the *H. F. Alexander* went across the Atlantic. The underwriters had no choice but to try it out, and there was no trouble, so I believe that this is the beginning of the acceptance of large size side ports on steamers running in what might be called foreign trade.

Intercoastal might be classified as foreign trade so far as the nature of territory you have to go through and it may be a valuable precedent. The new *California,* built by the International Mercentile Marine for intercoastal work, has large-size side ports. They are 8 ft. high and 8 ft. wide. That is high enough to run in any kind of rubber-tire freight-handling equipment. If this can be done in intercoastal service, I do not see why it should not be done in the Atlantic service. With side ports, as on the new *California*, there are beautiful passenger decks, with only one or two hatches on the whole ship made for large cargo. I am not speaking now of a ship to take locomotives, freight cars, and things like that, where the hatches must be big enough to take in long freight. I have seen the *Luckenbach* take 78-ft. long sheet steel piling for a drydock, pick them up, and lower them into the hold. For that there must be big hatches. This suggests another line of attack. Make the hatches so big that they are nearly all hatch, and then each draft can be set down where it is wanted.

There are several lines of attack on the freight-ship problem. The naval architects and ship operators should get together, and the mechanical engineers can help. There are so many different lines of approach that I do not know which one is going to be the answer; it depends on the particular trade. I believe that many ships now in use will become obsolete because of their cargo-handling cost as soon as they will be from the standpoint of obsolete engines. The field is practically untouched now. The side port has possibilities. I do not know what the underwriters are going to let us do about it. The Clyde line and different coastwise companies have been using side ports for years. Whether the word "coast" has any influence on the underwriters I do not know, but I believe with that precedent we can get side ports. With side ports the sling can be eliminated, and freight can be stowed in carload lots, inside the ship in such a way that there is a whole carload in one block. If the ship-loading crews do not stow it so that a carload can be found inside and if they do not bring the lot out intact on the pier, then somebody should be called "on the carpet" before the general manager. Canned goods may be loaded in such a way that they can be discharged to the pier intact as a carload when they come out. If it is necessary to sort according to the size of the prunes, or whatever it may be, at this end of the run, it is only necessary to sort through the area taken up by one carload, which can be done by hand. The freight does not have to be taken from one area to the next in this kind of sorting. If one would sort freight properly, he must stow the ship properly; in that way no castors or wheels of any kind will be needed.

# List of A.S.M.E. Transactions Papers Published Since January 1, 1928

*Below is published a complete list of the papers which have appeared in the various sections of Transactions since January 1, 1928, together with references to the issues of "Mechanical Engineering" in which abstracts of them may be found.*

# The Hydraulic Handling of Ashes

By ARTHUR MELLOR QUINN,[1] PHILADELPHIA, PA.

FUNDAMENTALLY, the handling of ashes by water has long appealed to the practical designer and operator of boiler plants as offering a means of carrying the refuse material without the use of conveying machinery. For years mine operators have pumped water from the mines, leading the water beneath the boilers, discharging ashes into the stream, whence the mixture flowed to low-lying ground or was allowed to discharge into a discarded mine shaft.

The absence of machinery, the elimination of labor, and the fact that the ashes are handled cold and dustless lend a powerful appeal, but these inherent advantages, until recent years, have been largely offset by serious objections.

Most plants are not as favorably situated for the process as were certain coal operators: thus they have no continuous stream of waste water in sufficient quantities and under enough head to carry ashes. If they have, they have no place to which the ashes may be washed. Large modern boiler houses cover considerable area, the boilers are in comparatively long rows, and a stream of water with sufficient pitch to maintain the required velocity means placing the boilers very high above grade. Thus a sluice channel having a pitch of $^3/_8$ in. per ft. will maintain a water velocity of about 12 ft. per sec.—barely enough (even with large proportions of water) to positively carry the ash. If now the boiler row is but 200 ft. long, the channel must drop more than 6 ft. from the upstream boilers to the end of the row; and in most instances this must be added directly to the total building height.

### Early Installations

Despite these drawbacks, however, certain outstanding plants prior to 1923 did install hydraulic methods of ash handling. This was done, the author believes, in most cases with boilers equipped with underfeed stokers having a grinder ash discharge, or with chain-grate stokers where no large clinkers were anticipated. The installations were successful as designed. The simplicity of the arrangement, absence of moving parts, elimination of labor, and the fact that the ashes were not handled loose with the attendant dust, dirt, and fog, became apparent at once and offset the disadvantages which came up. Briefly, the most serious of these disadvantages were as follows:

1 The stokers discharged ashes continuously, and it was necessary to pump water continuously. This resulted in high pumping cost—from 20 to 40 kw-hr. per ton of ash moved were the usual figures.

2 The water channels or sluiceways were pitched, which resulted in the necessity of setting the stokers very high above the ash basement, and consequently in high building expense.

3 In order to minimize the pitch of the sluiceway, and therefore the building height, water velocity was kept at a minimum to safely carry the ash. As a result the ash apparently half slid, half rolled along the bottom, and wear on the sluiceway liners was extremely high.

4 The sluiceway started at one end of the boiler house and continued to the other; further, it had to run continuously. Repairs, therefore, could be made only by handling the ash discharge from all the upstream boilers by other means (usually temporary, and as such, crude).

5 It was found with the sluiceway pitches ordinarily employed that clinkers of only limited size and density could be handled. Large and dense clinker, arch tile, or the like falling into the sluice would not move; smaller material following would wedge behind and a dam would soon form, and the sluicing water would back up and overflow the channel, carrying a dirty mixture of ash and water into the basement. (This is really a corollary of (4) and (5.))

6 If the sluice dammed at the downstream end, its operation was instantly destroyed for all upstream boilers, and as they depended upon the ashes being taken away as rapidly as discharged, the cumulative results were serious.

### Designs Employed in Modern Installations

Designers in the last five years have been continuously working to retain the inherent advantages of these earlier installations and eliminate these six major disadvantages. The designs employed by many modern installations are therefore listed below.

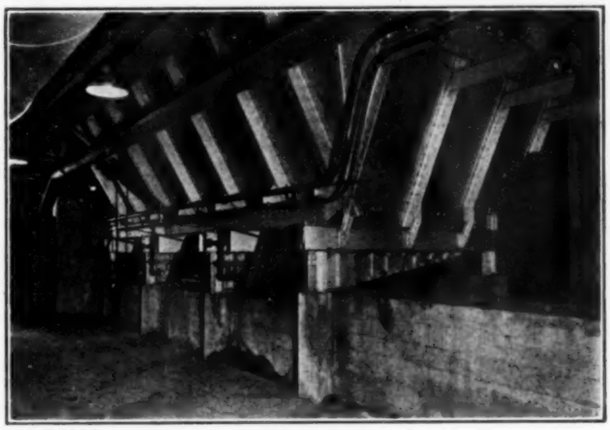

Fig. 1 Hydraulic Ash-Handling System Under a 2000-Hp. Boiler—Gould St. Plant of Consolidated Gas & Electric Co., Baltimore, Md.

(The furnace-bottom gates are opened and the ash dropped on the feed plates which are directly under the gates. The ash is then fed into a concrete sluiceway lined with nickel-cast-iron liners.)

1 To reduce the cost of pumping continuously, ash hoppers having from 8 to 20 hours ash storage between the stoker and the sluiceway are commonly employed; the instantaneous carrying capacity of the sluiceway being such that ashes accumulated in the hopper during hours can be run out in as many minutes. Many installations show water-pumping costs under these conditions of from one to two kilowatt-hours per ton of ash moved.

2 To overcome the necessity of pitching the sluiceway, water is introduced into it through nozzles at very high velocity by pumping it at high pressure (50 to 100 lb.), and then as the velocity drops along the sluiceway, introducing additional "booster" water. It was found that velocities of from 50 to 100 ft. per sec. could readily be maintained in a perfectly horizontal sluiceway for long distances (200 to 500 ft.).

3 Whereas ashes dropping into water moving at 10 to 12 ft. per sec. slide or roll along the bottom, it was found that with velocities of from 50 to 100 ft. per sec. the ash did not sink, but rather rode on top of the stream; abrasion of the sluiceway liners was thereby virtually eliminated.

4 As there was an ash storage of from 8 to 24 hours between

[1] Engineer, Allen-Sherman-Hoff Co. Assoc-Mem. A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Materials Handling Division, Philadelphia, Pa., April 23 and 24, 1928.

the stokers and the sluiceway, which could be discharged in as many minutes, there remained some 23 hours per day available for repairs, should they ever be necessary.

5 As the power available in a stream of water is a direct function of the water quantity and a function of the square of the water velocity, modern plants have almost eliminated the possibility of large, dense clinker or arch tile or the like failing to move

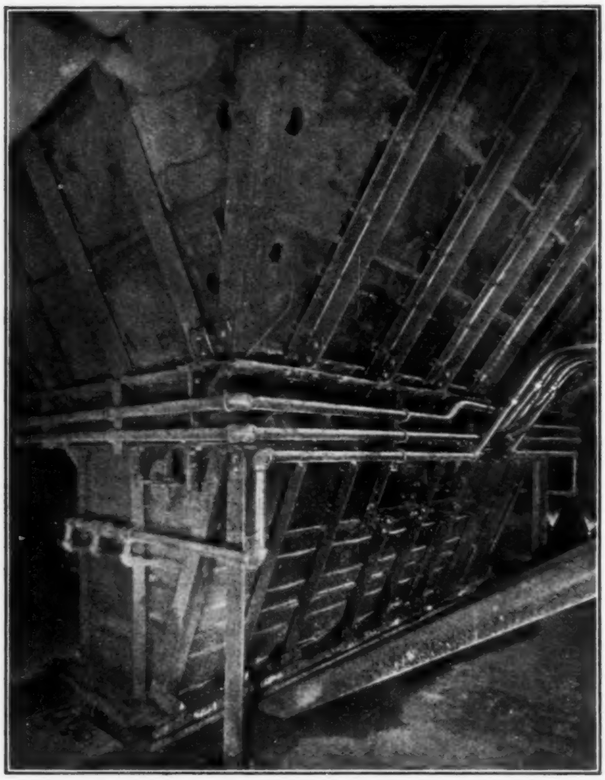

Fig. 2 Air-Cooled Furnace Bottom, Ash-Gate Section, Clinker Chamber, and Soot or Fine-Ash Collection System of Hydraulic Ash-Handling Installation in Plant of Sioux City Gas & Electric Co.

along the sluiceway. This becomes apparent when it is considered that the instantaneous quantity of water used is about the same, but its velocity in a modern plant is about in the ratio of 100 ft. per sec. to 10 ft. per sec. The instantaneous power, therefore, is about 100 times as great (the square of the velocity ratio), which means that a single clinker many times heavier can readily be moved. A modern sluiceway will readily carry a dense clinker weighing 50 to 75 lb., or to say it another way, will carry any stoker-refuse material passing 12-in. square grids.

6 Even should a modern sluice dam up (due to loss of water from the pumps or the like), operation of the plant is not seriously affected, as ashes will merely continue to accumulate in the ash hoppers until the water pressure has been reestablished and the dam broken up and discharged, when the usual method of ash discharge will be continued.

To summarize: Earlier ash sluicing was continuous and employed pitched sluiceways, which developed certain disadvantages resulting in the general adoption in modern plants having ash-storage hoppers above the sluiceway, of intermittent operation of the sluiceway, and (by use of high-pressure water producing high velocity) of horizontal sluiceways.

A most serious difficulty developed in storing ashes so that sluiceways might be intermittently operated. The original idea was that ash gates would control the flow of the ashes from the hopper to the sluice. However, it soon became apparent that it was virtually impossible by simply opening the gate which controlled an accumulation of several tons above, not to instantaneously overload the carrying capacity of the sluice below. It was therefore necessary to develop a positive means of controlling the instantaneous flow of ashes from the hopper above in proportion to the instantaneous carrying capacity of the sluice. Two general schemes have been successfully employed.

The first consisted in dropping the ashes into a mechanical feeder provided with rolls which would feed directly in proportion to the speed at which they were driven. This scheme has the double advantage of crushing any clinker which might be too large for the sluiceway to carry.

Another extremely simple and positive scheme (which has the advantage of requiring no machinery for feeding) consists in eliminating the ash gates altogether, and allowing the ashes from the stoker to drop to the slightly sloping plates forming the bottom of the ash hopper. When the hopper is full, water jets (fed from the same source of water supply as that feeding the main-sluiceway carrying nozzles) undermine the accumulated ashes, both ashes and water flowing into the sluiceway. As the undermining feedwater is from the same source as the carrying water, that is, at the same pressure, it is apparent that by proportioning the two quantities, any feeding rate may be obtained which will always be in proportion to the carrying capacity of the sluice beneath.

This scheme can only be used where no large proportion of the ash will contain clinkers individually exceeding 50 to 75 lb. in weight. Usually it is not applicable to underfeed stokers using dump-plate ash discharge. Mechanical feed (such as grinders) should be employed under this condition.

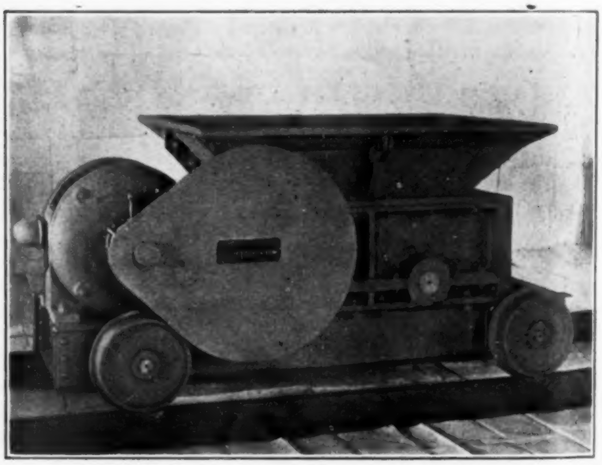

Fig. 3 Clinker Grinder on Proportioning Car Used for Feeding Ash From a Dump-Plate Stoker to a Hydraulic Ash-Handling Sluiceway

### Handling Ash From Pulverized-Fuel Furnaces

Modern hydraulic ash handling is particularly applicable to ash from pulverized-fuel furnaces. It has been found that on the average about 25 per cent of the total ash in the fuel where powdered coal is employed is collected in the ashpit proper. Another 15 to 20 per cent is collected from the second pass of the boiler, from hoppers beneath economizers or air heaters, from flues, and from the base of the stacks. A horizontal sluiceway may thus readily be used to collect dust from many sources through comparatively small pipes run almost at will. By carrying this dust mixed with water and virtually as a fluid, none of the

problems of flow angles along various substances enter—all of which results in amazing simplicity of design.

Of particular importance, where pulverized coal is burned, is the fact that in a modern hydraulic ash-handling system the ashes and dust are not handled loose; the system is totally enclosed and the refuse ends its trip under water. The impracticability

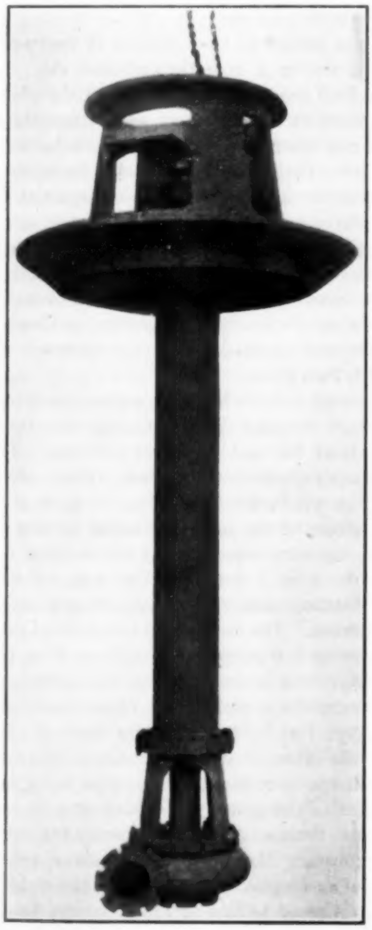

Fig. 4 Vertical Manganese-Steel Pump Used for Discharging Ashes Either to Fill or to Tanks

of handling such ashes by dropping them dry and loose into cars or an open conveying system can readily be seen when it is appreciated that a great proportion of the ashes in such a coal-burning system are as impalpable as talcum powder or cement dust. Handled loose they float in suspension in the air, permeating the entire power house, with probable serious effects on moving machinery.

In handling ashes beneath pulverized-fuel furnaces attention is particularly called to the necessity of having an ash storage space well protected from the direct heat of the furnace; otherwise the ash may fuse and serious trouble result. It is always necessary to have an ash gate between the ash-storage hopper and the sluiceway where pulverized fuel is used, to prevent excess air entering the furnace.

The Buffalo General Electric Company have been successful in handling ash as molten slag by means of hydraulic ash handling. The furnace is of the well type, and ash melts and accumulates as a molten pool at the bottom of the well. This is tapped off daily, dropping to high-velocity water jets which instantaneously chill and disintegrate it. The chilled particles are carried by an ordinary high-velocity horizontal sluiceway to a sump, from which point they are pumped by manganese-steel centrifugal pumps to a fill some 1100 ft. distant.

### Ash Disposal

It is now necessary to consider the final disposition of the ashes after they have been hydraulically accumulated into a central sump. There are several well-developed means, as follows:

1 The ashes and water, where elevations and distances permit, may be sluiced direct to the fill, the ashes remaining and the water leaching back into the ground or flowing to creek or river.

2 The ashes and water, where elevations or distances or both do not permit sluicing direct to the fill, may be sluiced to a central sump and pumped by manganese-steel pumps to the fill, the ashes remaining and the water being disposed of as before. This scheme requires a very small sump, as ashes and water are taken out as fast as they come in.

3 The same as (2) except the ashes and water are pumped into an overhead bin, the water flowing out (through water-collecting ash gates at the bottom of the bin) to the sewer, and the ashes remaining to be dumped later into railroad cars, auto trucks, or the like for final disposition. As in case (2), a very small sump is required.

4 The ashes and water may be sluiced to a large sump, the ashes stored therein, and the water allowed to overflow to the sewer. Of course, combinations of any of these schemes may be employed, but the four cases outlined are fundamental.

Where water is a valuable commodity it may be recirculated after dropping out the ashes. In such a case not more than 1 lb. of water per 10 lb. of ash moved is required as make-up.

In closing, it is interesting to note that the material handling section of the Prime Movers Committee of the N.E.L.A. said in their 1926–27 report that of 38 plants examined that were built prior to 1924, about 15 per cent used hydraulic means of ash handling, whereas of 24 plants investigated that were built since that time, 50 per cent employed this means. The cost analysis showed that of all the ash-handling means employed in all the plants examined, the hydraulic showed 30 per cent less cost per ton of ashes handled than the next best means.

## Discussion

Charles H. Bigelow.[2] About 30 years ago, while I was with the West End Street Railway Company in Boston, we designed a power plant at Charlestown and there we installed sluiceways under all the boilers through which we discharged the water from the condensers. They were hand-fired grates; the ashes fell into the sluices and were carried out, and that part of it worked successfully. The water discharged upon the flats; there was a bulkhead quite a way out, and we thought we could fill up the flats without trouble, but unfortunately the water carried the ashes too far out into the channel. The Harbor Commission got after us, and we had to stop it. We had an unlimited supply of water while we were running, all our discharge water from the condensers flowing along these channels, and it worked very well as far as it went.

### Author's Closure

As to Mr. Bigelow's comments, I understand that there have been various plants in the country that have used condenser water and in some cases waste water from stills, etc., the water being led in a stream under the boilers, from which the ashes are dropped, and carried to a fill. Mr. Bigelow brought out the fact that the ash carried quite a distance out into the channel.

[2] Plant Engineer, Spicer Mfg. Corp., South Plainfield, N. J. Mem. A.S.M.E.

That is a peculiar feature of hydraulic ash disposal. When we think of it, ash travels just as sand does.

I visited the Ford Motor plant in St. Paul about two years ago, a year and a half after we had installed a complete hydraulic ash-handling system. The ash is moved from two boilers and two gas generators to a small sump, from which it is pumped to a fill. I expected to find the ash in a large pile at the discharge end of the pipe line, but instead it had drifted to various places and at that time had built up 8 or 10 in. around the trees for an area of approximately half an acre.

Harry S. Ford[3] asks whether the 14 cents per ton of ash handled at Media, which I mentioned in my oral presentation of the paper, includes the total cost. I might say that it does not, and that he also misunderstood me. It is 14 cents a day for the cost of pumping the water, and that is the only cost other than the original installation cost of the particular job. There has been absolutely no maintenance at that particular plant, and it has been in operation over a year and a half. The ash is sluiced 500 ft. to fill in 7 minutes or less per day.

As to the maintenance charge of which Mr. Ford speaks, the job at the Ford Motor Company has been in use for about three years, and to my knowledge we never shipped them any spare parts or equipment for making repairs to their installation. They use pumps and discharge the ashes alongside the Mississippi River bank.

Mr. Ford also brings up the matter of abrasion. As I stated, the abrasion is virtually eliminated. Here in Philadelphia we have a plant in which 50 tons of ashes a day are handled. Originally, we installed in the sluice at this plant 160 ft. of quarter-round liners. These were designed with the idea that after the bottoms of the liners wore they could be reversed and the side be used then at the bottom. There was also about 185 ft. of half-round liners. However, owing to the velocity of the water and the effectiveness in moving the material, it would also move the quarter-round liners to the sump after the bottom of the liner had worn enough to allow the water to get beneath them. Now, at the time those liners were installed, ordinary cast iron $^5/_8$ in. thick was used. However, the full half-round liners that were also installed in the plant have been in use with about 50 tons of ashes a day passing over them, and they have been renewed this year. These are the liners that are in the mouth of the sluice itself, at the discharge end—say, the last 50 or 60 ft. of the sluice. This means that it took almost three years to wear down half-round liners only $^5/_8$ in. thick. At present we are supplying nickel liners $1^1/_8$ in. thick in place of the ordinary cast-iron liners.

Mr. Ford also makes mention of the shut-off gate under the hopper. He states that in case such wear took place, there would be about 23 hours a day for repairs because the gates could be kept closed, and desires to know what would happen when no gates were installed. Mr. Ford is evidently referring to a powdered-fuel furnace. In this case, feed plates are set at an angle of approximately 15 deg. and are located beneath the ash gates. These gates seal off the bottom of the furnace. Without gates, another type of seal would be necessary to give the proper control of furnace gases. Consequently, we obtain time for the removal of old liners and the installation of new liners in relation to the carrying capacity of the hopper itself. It is very easy to install these liners as 30 ft. of liners can be installed by means of turnbuckles in $2^1/_2$ hours.

Mr. Ford also brings up the question of feed nozzles, not undermining but boring a hole through the ash. Originally we attempted to feed the ash from the top of the plate downward. This did not meet with real success, as at times the whole charge of ash would run down in an avalanche, similar to dropping the ash directly from the gates themselves. An improvement over that design was the installation of two nozzles at the lower end of the feed plate, one at each side, with the streams crossing each other at the upper end of the feed plate; this water undermined the ash from the lower end of the feed plate, and positive control of the quantity of the ash fed was obtained.

Since that time we have developed an oscillating nozzle and use only one hand-operated or power-operated nozzle at the bottom of each feed plate.

The next question is on how the water was drained from the tank. Mr. Ford is quite right in saying that the discharge to the tank is about 600 gal. of water per min. The statement made in the paper should be amplified. There are two methods of doing it, the preferable one being to have a weir running around the bottom of the tank, the water flowing over the weir and then running to waste, or being recirculated in the system. However, in the tank I described this was not the case. The tank was an existing tank and the aforementioned arrangement was not adaptable. The water was taken from its top level by means of lowering a 6-in. pipe through an 8-in. pipe. On top of the 6-in. pipe was a cross-fitting, and attached to the top flange of the cross-tee a piston rod, which maintained the cross on the 6-in. pipe just below the water level of the tank. The two inlets of the cross allowed the water to enter the 6-in. pipe and then discharge to waste, the 6-in. pipe being lowered to the ashes by means of the piston rod which was operated with hydraulic pressure, through a manually controlled valve.

The next question Mr. Ford asks is about recirculating the water. This is accomplished by allowing the water to pass over and under a series of baffles at low velocity, to allow the ash particles to drop out, and then repumping the clear water resulting back to the sluice nozzles. We require about 1 lb. of water in actual "make-up" for each 10 lb. of ash handled, based upon the average operation where the ashes are quenched prior to sluicing. The circulating arrangement has been in use in Harrisburg more than 10 years, and as to the effect on the pumps, I cannot definitely state. I might say that the new Kips Bay Station in New York is going in on the same basis.

The last question Mr. Ford asks is again about maintenance and how to compare costs. I personally have not compared these costs. I have used the report of the Prime Movers Committee. As to how they base their analysis, I am not certain.

# Modern Handling Methods of Railroad Transportation

## Meeting Freight-Traffic Problems at the Terminal Discussed—Use of Unit Containers in Transporting Merchandise in L.C.L. and Full-Carload Lots

By G. C. WOODRUFF,[1] NEW YORK, N. Y.

OVER the great golden dome of the Transportation Building of the World's Fair of 1893 there was the caption: "The easy progress of men and things from place to place makes a nation strong and great." This to a very great degree at that time typified, and during the succeeding years has continued to typify, the advance of America through the current and never-ending improvements in transportation.

Other nations may have elements which would seem to make for prosperity and advancement, such as education, fertile acres, and extensive territory, but a comparison of the progress of such nations with the progress of these United States in the past fifty years would show without question that because of its transportation the United States has advanced in a degree far exceeding the advance of other nations of the world.

The term "transportation," however, has perhaps been used in too narrow a sense in that it has essentially been confined to the movement between distinct places rather than to all elements included in transportation, such as for instance the movement within a restricted area or a given terminal, which embraces all methods for the better and more economical handling of the goods which are to be or have been transported. Therefore any undertaking which would benefit those most vitally interested in terminal handling, namely, the shipping and receiving public and the railroads, would be properly considered as an important advance in transportation.

The request to prepare a paper on this subject mentioned certain phases which it was desired should be discussed, and as only passing mention may be made of many of the activities, the features of largest importance and greatest interest to mechanical engineers will be stressed.

The handling of unit containers will first be discussed, and in that discussion there will necessarily be brought in some of the other elements, such as overhead cranes, electric lift trucks, and motor trucks, for it will be shown that each and all serve an important part in the ultimate development of this one phase of terminal handling.

The handling of unit containers may be subdivided into two parts, the handling of merchandise freight or what is commonly known as less-than-carload-lot traffic, and the handling of rough or bulk freight in carload traffic.

### Handling Merchandise Freight

For the past fifty years or more the methods in handling merchandise freight have not been changed to any marked degree, in that packages of various kinds, shapes, and sizes have been tendered at the railroad platform, taken by railroad labor after unloading from the shipper's truck, and either directly loaded into a car or more frequently placed upon the freight-house floor until the car could be loaded, and then trucked to the car for relatively long distances and stowed in the car. Owing to the usual limitations in available extra space, particularly at larger terminals, in many instances the freight must be loaded into the car currently as offered, which often has resulted in an ill-assorted and badly loaded car, because it was not possible to reassort and properly load the freight to the best advantage.

Obviously if heavy packages were offered late in the day and the car was two-thirds loaded, it would not be practical to unload the car and reload it on account of the cost and lack of time, so that in actual practice another car would be loaded, resulting in relatively light loads for both cars.

The freight having been loaded in the car, the car would be transported sometimes to destination and sometimes to a transfer, where the freight would be taken out and there reloaded in another car, in the case of a transfer, or unloaded from the car at the destination point, placed in the freight house, and later on picked up again and taken to the doorway for delivery to the consignee's truck. In the case of the transferred freight an intermediate unloading and rehandling would also be necessary.

A study of the cost of handling L.C.L. merchandise freight made during the Railroad Administration developed that for 88 representative cities in the Eastern section, the amounts which must be charged against the handling of L.C.L. merchandise would be on the average 10.4 cents per 100 lb. at each end of the route. Obviously a railroad having the point of origin and the terminal both on its rails would be saddled with the extra expense of 20.8 cents per 100 lb. for mere terminal handling.

In addition it was pointed out by Attorney Examiner Flynn in Docket 18000 in the matter of motor-coach and motor-truck operation, incident to general discussion of L.C.L. tonnage, that "although the less-than-carload tonnage in 1924 constituted $3^1/_3$ per cent of the total tonnage handled by Class 1 steam railroads, it is stated that 25.7 per cent of the railroads' equipment was used to handle it and 32.2 per cent of claims paid were on this less-than-carload traffic." It will be observed, however, that the relationship of tonnage, cars used, and claims paid on this L.C.L. merchandise is altogether out of proportion.

In addition the loading of merchandise cars to specified points owing to the necessity of handling, as outlined in the first part of this paper, has necessarily resulted in very lightly loaded cars and a duplication of service without consequent proper relative revenue. Further, the investment in terminal facilities, including warehouses, tracks, and other operating facilities, is much out of proportion to the tonnage and revenue resulting, and in addition the railroads as a whole are consistently faced with demands for increased capital expenditures for facilities to take care of the L.C.L. merchandise business. In many of the larger cities such facilities can be obtained only at almost prohibitive prices, if at all.

Such a situation has naturally been a matter for deep thought by those responsible for the proper operation and monetary returns by the railroad. It would have been an easy matter to have corrected this situation to a considerable degree by holding freight over or doubling it up, but in such a procedure the interest of that factor most vitally concerned would not have been properly taken care of, namely, the public, and in the final analysis as a public servant the railroad owes its first duty to that public and

[1] Assistant Freight Traffic Manager, New York Central Railroad Company.

Presented at the First National Meeting of the A.S.M.E. Materials Handling Division, Philadelphia, Pa., April 23 to 24, 1928.

must give reasonable service, bearing in mind the commercial necessities of this particular traffic.

Since the War, with the rehabilitation of the railroads generally it is perhaps fair to say that the brand of service offered has never been better, and the public has been led, and properly so, to expect continuous daily reliable service, so that they have been in a position to cut down inventories and depend on regular receipts for their daily needs.

There have been many things thought of, and among them—and perhaps presenting, at least to as large a degree as any, favorable comment—is the unit container as typified by the L.C.L. merchandise container, which, following a number of years of development starting back of 1922, first was in operation in 1922 in a very limited way, and by constant experimentation and endeavoring to change for the better has been gradually improved and extended until it is being increasingly used in handling L.C.L. merchandise traffic between important centers.

Picture a large box or a container having a capacity of 438 cu. ft., with outside dimensions of width 7 ft. $2\frac{1}{2}$ in., height 8 ft. $2\frac{1}{2}$ in., length over guides 9 ft. $3\frac{1}{2}$ in., and with inside dimensions of width 7 ft., height at eaves 7 ft. 1 in., length 8 ft., 10 in., provided with eyes at the four corners, with straps by which an overhead crane or other conveyor can lift it from the truck to the car or from the car to the truck, and fitted into place on the car by means of guides and slots so each is firmly held and all possibility of side sway or other change of location is avoided.

Such containers are handled on a car about 47 ft. long by 9 ft. $3\frac{1}{2}$ in. wide, of low-side gondola type, equipped with guides into which the containers fit. The containers have a tight door and are leak-proof in every particular. The doors are locked and the method of carrying the containers on the car makes it impossible to open them in transit. This is important in that it absolutely does away with opportunity for pilfering while in the railroad possession, and as it is locked by the shippers and unlocked by the consignees with their own locks and keys, the possibility of their being opened by any one on the truck at either end of the route is practically nil.

In addition, as six of these containers are used on the present type of car, the liability of damage claims is reduced to almost nothing in that the goods to be transported are divided into six units, which in effect are protected against each other by double bulkheads. The advantages of this method of transportation are of value both to the transportation agency, which is the railroad, and to the public, which is the shippers and the consignees. Each container can handle a maximum load of 8500 lb. of miscellaneous freight, and the rate structure, as developed, makes it advantageous to the shipper or receiver to have the containers loaded as nearly full as possible, with the results that if each container should be loaded full there would be a car of 51,000 lb. of mixed merchandise as compared with the ordinary loading of merchandise freight in box cars of about 15,000 lb.

The goods are loaded in a container by a shipper and are unloaded from the containers by the consignee so that in comparison with ordinary merchandise freight that is loaded into the cars by a carrier and similarly unloaded from the cars by a carrier, the saving in labor alone is important.

In addition, if in ordinary transportation the carriers had the equivalent of the amount of freight shown as capable of being transported in one unit of six containers per car, they would in their ordinary method of handling have to use at least two to three merchandise cars to transport such aggregate freight, which would mean in addition to the capital investment in one or two extra cars the actual road-run cost of the operation of these cars as against the one car, not to mention the extra switching at each end of the line and the house space taken up by the extra cars. Further economies are possible to the railroad in that the billing is by container rather than by item, and it seems needless to point out that with an average expense per billing item of about 15 cents the saving of hundreds of billing items would mean a radical economy from the accounting department standpoint.

From the standpoint of the user of the containers, the shipper or the consignee, the advantages and economies are equally important, because a basis of rates has been developed which departs from the usual official classification basis and is on the mileage and bulk loading of miscellaneous articles in the container, all articles proper to be transported in the container being charged at the same rate, which is a certain figure per mile for a certain fixed minimum amount of tonnage in the container. These charges are increased as the weight increases to the maximum, but the resultant rate if reduced back into cents per 100 lb. is relatively less per 100 lb. as the containers are loaded to or nearly to their maximum. In addition the charges are on the weight of the contents of the container, and it is not necessary in container shipments to pack the goods in the same manner as prescribed by the official classification or in ordinary railroad shipping, and therefore light packages or simply paper wrappings can be used, with a considerable saving in that part as well.

The lack of pilferage is equally important to the shipper or consignee, and the almost total cessation of damages presents an attraction in the service. Further, from a handling standpoint, the containers are loaded at the shipper's place of business, trucked to the railroad, either by the shipper or under contract with outside truckman, the railroad having no part in this undertaking, put as a lot on the car, and at destination trucked to consignee's place of business. Here they can be unloaded on the truck or can be taken off the truck and put on the consignee's platform for handling at his convenience.

It is becoming generally recognized that the use of unit containers is of increasing importance, and the development of the L.C.L. merchandise container has appealed to the railroads as it is being used in larger numbers each year. The point of view of the railroads is expressed in the following quotation from an address at Dallas, Texas, on October 18, 1927, by the chief executive of one of the principal railroads of the country:

"We are doing new things. For instance, the railroads are developing new plans of packing in containers which can be lifted from a motor truck in one city one evening, placed in a car and moved overnight, and early the next morning taken off the railroad car and put on another motor truck and delivered to destination promptly. This development of container transportation promises to revolutionize many of our methods. It may ultimately relieve us of one of the most expensive of our activities in the handling of less-than-carload freight at transfer stations."

The use of the L.C.L. merchandise container becomes increasingly possible at the smaller stations as ways and means are developed for best handling it, and it is felt that ultimately it will to a large degree solve the question of the expensive wayfreight handling to and from such small stations, and in addition present a means by which service to and from such small stations from and to the large cities of the country may be put on a parity with service from the larger ones where straight cars now are run.

As an illustration, on a railroad A, for instance, six relatively small towns, important commercially, have a limited volume of freight for six large receiving centers in the West, but no one town has enough, daily or semi-weekly or tri-weekly, to load a straight car to such destinations.
